PREFACE

Three objectives have guided the writing of this book—the correlation of pharmacology with related medical sciences, the reinterpretation of the actions and uses of drugs from the viewpoint of important advances in medicine, and the placing of emphasis on the applications of pharmacodynamics to therapeutics.

Although pharmacology is a basic medical science in its own right, it borrows freely from and contributes generously to the subject matter and technics of many medical disciplines, clinical as well as preclinical. Therefore, the correlation of strictly pharmacological information with medicine as a whole is essential for a proper presentation of pharmacology to students and physicians. Furthermore, the reinterpretation of the actions and uses of well-established therapeutic agents in the light of recent advances in the medical sciences is as important a function of a modern text book of pharmacology as is the description of new drugs. In many instances these new interpretations necessitate radical departures from accepted but outworn concepts of the actions of drugs. Lastly, the emphasis throughout the book, as indicated in its title, has been clinical. This is mandatory because medical students must be taught pharmacology from the standpoint of the actions and uses of drugs in the prevention and treatment of disease. To the student, pharmacological data *per se* are valueless unless he is able to apply his information in the practice of medicine. This book has also been written for the practicing physician, to whom it offers an opportunity to keep abreast of recent advances in therapeutics and to acquire the basic principles necessary for the rational use of drugs in his daily practice.

The criteria for the selection of bibliographic references require comment. It is obviously unwise if not impossible to document every fact included in the text. Preference has therefore been given to articles of a review nature, to the literature on new drugs, and to original contributions in controversial fields. In most instances, only the more recent investigations have been cited. In order to encourage free use of the bibliography, references are chiefly to the available literature in the English language.

The authors are greatly indebted to their many colleagues at the Yale University School of Medicine for their generous help and criticism. In particular they are deeply grateful to Professor Henry Gray Barbour whose constant encouragement and advice have been invaluable.

The use in this volume of certain portions of the text of the United States Pharmacopoeia is by virtue of permission received from the Board of Trustees of the United States Pharmacopoeial Convention. The said Board of Trustees is not responsible for any inaccuracy of quotation, nor for any errors in the statement of quantities or percentage strengths.

Permission to use for comment in this volume certain parts of the text of the National Formulary, Sixth Edition, has been granted by the Committee on Publications by authority of the Council of the American Pharmaceutical Association.

The quotations from and references to New and Nonofficial Remedies are made with the permission of the Council on Pharmacy and Chemistry given with the provision that the Council is not responsible for any inaccuracies of quotations or any errors in the statements of quantities, percentages or strengths.

The PHARMACOLOGICAL BASIS *of* THERAPEUTICS

SECTION I

INTRODUCTION

CHAPTER 1

GENERAL PRINCIPLES

SCOPE OF PHARMACOLOGY

The subject of pharmacology is a broad one and embraces the knowledge of the source, physical and chemical properties, compounding, physiological actions, absorption, fate and excretion, and therapeutic uses of drugs. A *drug* may be broadly defined as any chemical agent which affects living protoplasm, and few substances would escape inclusion by this definition.

For the medical student and physician, however, the scope of pharmacology and the number of substances to be regarded as drugs are more restricted than indicated by the above definition. The physician is concerned with actions and uses of drugs in the therapy of disease. Obviously his attention is directed toward channels different from those of the pharmacist who compounds drugs, the chemist who synthesizes new medicinals or the botanist who studies the mechanisms by which plants form potent therapeutic agents. Therefore, the study of pharmacology should be approached with specific aims in mind. Before individual drugs are discussed it is fitting to consider the component parts of pharmacology in order to appreciate how best to approach the subject from the standpoint of the interests and requirements of the medical student and practitioner.

The subject of pharmacology in its entirety may be divided into pharmacognosy, pharmacy, pharmacodynamics, pharmacotherapeutics and toxicology.

Pharmacognosy is that branch of pharmacology which deals with the physical characteristics of crude drugs. It is purely a descriptive science. Inasmuch as most crude drugs are of plant origin, pharmacognosy deals largely with the botanical sources of drugs and the characteristics of the plants from which they are obtained. The interests of the physician in pharmacognosy are limited. At one time it was essential for a member of the medical profession to have a broad botanical knowledge, for it was then within his province to select the proper plants and to make from them crude drug preparations. If William Withering had not possessed training in botany, the introduction of digitalis into medicine might have been long delayed. Fortunately, the physician today is not confronted with the problems of pharmacognosy. For him, the drugs of the world are gathered, manufactured and marketed in forms which permit economy, stability, uniformity and ease of administration. However, scientific curiosity should stimulate the physician to gain some conception of the sources of the medicinals which he employs, and often this knowledge proves both interesting and helpful.

Pharmacy deals with the art of preparing, compounding and dispensing medicines. This work at one time lay within the province of the physician, but now it is relegated almost completely to the pharmacist. However, the physician must have a basic knowledge of the art of pharmacy in order to write intelligent prescriptions. He must know the form in which a drug is best administered, what solvents are suitable for a particular medicinal agent, whether two drugs can be placed in solution together without producing an incompatibility, etc. Too often the physician shirks his responsibility in this regard, and resorts to the practice of prescribing "ready-made" mixtures of drugs sold by pharmaceutical houses under trade names. Often the proportion of drugs in such a prepared mixture is not exactly that which is desired. Trade-marked products are also likely to be expensive. The physician gives up his prerogative of individual treatment and does not favor the best interests of his patient when he fails to translate his knowledge of pharmacology into a prescription best suited for the needs of a particular individual. It requires little additional effort in the study of pharmacology to master the few details essential to the correct writing of prescriptions.

Pharmacodynamics is the study of the actions of drugs on the living organism. It is one of the youngest of the experimental medical sciences and dates back only to the latter half of the 19th century. Pharmacodynamics is a border science. It borrows freely both from the subject matter and technics of physiology, physiological chemistry, pathology and bacteriology. It is unique only in that attention is focused on the actions of drugs. As the name implies, the subject is a dynamic one. The student who studies it in a static manner, who merely memorizes the actions of drugs, is foregoing one of the best opportunities for correlating the entire field of preclinical medicine. For example, the mechanism of action of diuretic drugs and their therapeutic indications and limitations can only be fully understood when one has a basic understanding of the physiology of the kidney and the pathological physiology of edema formation. Yet no greater insight can be gained into the physiology of the kidney than that obtainable from a study of the actions of diuretics. As an even more striking example may be cited the action of digitalis on the heart. The study of the cardiac effects of digitalis leads to a better understanding of the physiology of conduction in cardiac muscle, the factors controlling heart rate, diastolic size and cardiac output and the alterations in the functions of the heart and vascular system secondary to congestive heart failure. The pathological physiology of cardiac decompensation can be more thoroughly appreciated by observing the restoration of cardiac function by digitalis and the rapid reversal of events which proceeded slowly over a period of months or years. Again, no better understanding of the physiology of the autonomic nervous system can be obtained than by studying the actions of drugs which prevent the responses of effector organs to nerve impulses, and drugs which mimic the effects of nerve impulses. Conversely, the laborious task of learning the numerous actions of a score or more of autonomic drugs is rendered unnecessary by correlating a basic knowledge of the manner in which these drugs alter the functional activity of structures innervated by autonomic nerves with the known responses of the same structures to nerve stimulation.

Pharmacodynamics also deals with the absorption of drugs, their fate in the body and the mechanism of their excretion. Here a number of principles of physiological chemistry can readily be applied to an understanding of the metabolism of substances foreign to the body.

There are many phases of pharmacodynamics which are of minor interest to the physician, among which is *comparative pharmacology*. From an academic point of view, the action of a drug on frogs may be just as important as its effect on man. The physician, however, is interested in the actions of drugs which are useful in therapeutics, and to him comparative pharmacology is important only in so far as the results obtained have clinical application. Striking advances have occurred in the field of human pharmacology, largely as a result of new methods of experimental approach. When digitalis was first studied, the frog heart was utilized. Much basic information was gained, but the modern interpretation of the actions of the drug on the human cardiovascular system was forthcoming only after the effects of digitalis had been studied in man by means of special technics for measuring cardiac size and output, circulatory velocity, venous pressure, peripheral resistance and changes of conduction in cardiac muscle. As a result, many of the earlier conceptions were discarded or revised. Numerous other instances could be cited in which it was necessary to change the older concepts of the actions of drugs obtained from animal experimentation when the drugs were restudied in man. Therefore, in the following pages, emphasis is placed on human pharmacology.

The subject of comparative pharmacology, however, is not to be neglected. Some of the most esoteric observations on the actions of drugs in lower species can be applied to human pharmacology. For example, the fact that a chicken is anesthetized by barbital for an indefinite period because of its inability to excrete the drug has its clinical counterpart in the patient with inadequate renal function who receives a barbiturate which depends upon renal elimination for its duration of action. The responses of the gastro-intestinal tract of a primitive fish, the tench, to certain autonomic drugs permit broad interpretations which help to clarify the basic mechanism of action of these drugs on smooth and striate muscle.

Another ramification of pharmacodynamics is the correlation of the action of drugs with chemical constitution. This is a basic field which has only begun to be developed, and the one from which the greatest contributions of pharmacology to medicine will probably arise. The relation between chemical structure and pharmacological actions is discussed in connection with the individual drugs. This is done with the realization that many students and physicians have neither the interest nor the chemical background fully to appreciate the importance of the subject. It is hoped, however, that an occasional reader will be stimulated, by the inclusion of this subject, to a deeper interest in pharmacology.

Pharmacotherapeutics is the study of the uses of drugs in the treatment of disease. Pharmacotherapeutics is no longer practiced in an empirical manner, but rather rational drug therapy is based wherever possible upon a correlation of the pharmacodynamic actions of drugs with the pathological physiology of disease. Only in exceptional cases are drugs still used on an empirical basis. In the medical curriculum, pharmacodynamics is usually taught before the student has had clinical courses. For this reason pharmacotherapeutics is often neglected in the teaching of pharmacology on the false premise that the student does not have the necessary clinical background. This is true only if one has empirical therapy in mind. It is during the study of pharmacodynamics that the student has the best opportunity to correlate the actions of drugs with the knowledge that he has already gained of the pathological physiology of disease.

Toxicology is the study of poisons. This broad aspect of pharmacology is discussed separately.

MECHANISMS OF DRUG ACTION

One of the most fascinating and difficult fields of pharmacological research is that which deals with the mechanisms of drug action. In a few instances, the fundamental manner in which a drug produces a given effect is obvious. For example, the efficacy of mercuric chloride as an antiseptic lies in the ability of the mercuric ion to precipitate the bacterial protein. No ready explanation is available, however, to elucidate the manner in which central nervous system depressants produce unconsciousness, or digitalis stimulates the muscle fibers of the heart. In the last analysis, too little is known of cellular physiology to permit an interpretation of the mechanism of action of those drugs which alter cellular functions. However, a few positive statements pertaining to the more general concepts of this subject can be made.

Cellular Response to Drugs. The typical response of a cell to a drug is definitely limited by the functions of that cell. It can be stated with certainty that drugs cannot impart new functions to cells or tissues, but rather can only stimulate or depress cellular activity. The degree to which drugs stimulate or depress can be controlled by dosage and in this way the intensity of action of a drug can be adjusted so as to be of therapeutic value. As pertinent examples may be cited the depressants of the central nervous system which are of clinical value because their degree of activity can be regulated. Any desired intensity of depression can be obtained and this may be varied from sedation through somnolence to anesthesia sufficiently deep to allow performance of major surgical procedures. Conversely, the level of function of the nervous system can be raised by drugs which stimulate the cerebrospinal axis. By a proper selection of drug and dose one may obtain any desired degree of excitation from barely detectable stimulation to severe convulsions.

Disease is often characterized by a change in the functional capacity of certain tissues. For example, congestive heart failure is characterized by an underlying impairment of the contractile power of the myocardium. Inasmuch as a cardiac stimulant can do no more than enable the heart fibers to contract up to the maximal physiological limit of which they are capable, the therapeutic value of digitalis in cardiac decompensation is dependent upon and limited by the inherent functional reserve of the myocardium.

Selective Action of Drugs. Most drugs are selective in action, that is, they affect only a specific tissue. Thus there are drugs which act primarily upon smooth muscle, skeletal muscle, nerve, glands, renal tubules, etc. The antidiuretic principle of the posterior pituitary may be taken as an example of a drug with a highly selective action. As little as 0.0025 mgm of posterior pituitary is capable of inhibiting water diuresis in man. The same dose of the drug affects no other functions of the body. The exact mechanism of this selectivity of action is unknown, but it is believed that there may be a special affinity of a chemical nature between the drug and the responding cells. For example, heart muscle responds to very low concentrations of acetylcholine. It has been calculated that an amount of acetylcholine which could cover only $\frac{1}{6000}$ of the surface of a cardiac fiber can alter the function of that cell. It is therefore believed that acetylcholine acts on special receptors, and inasmuch as the drug is a strong base it is postulated that the receptors may be carboxyl groups. Analogous chemical affinities may exist in all instances in which drugs show selective actions on particular tissues.

Sites of Drug Action. Certain drugs act directly on effector cells; others exert their actions in a remote and roundabout manner. In many instances the exact site of action is unknown. Those substances which act directly upon the responding tissue have two possible sites of action, the surface or the interior of the cell. The very rapid response of effector organs to certain drugs suggests that the site of drug action is extracellular. On the other hand, there is evidence that tissues respond to many chemicals only after they have penetrated the cellular membrane.

Again, the site of action of a drug may be removed from the tissue which ultimately responds to give the desired effect. For example, a substance may lower blood pressure by acting on the vasomotor center. A respiratory stimulant may act on the carotid body rather than on the medulla. Also drugs may exert their effects in an indirect manner by promoting or preventing the action of another substance. Physostigmine stimulates structures innervated by cholinergic nerves not directly but by inhibiting the enzyme which normally destroys acetylcholine. Atropine inhibits the same structures by preventing the access of acetylcholine to the effector cells.

Relation of Chemical Structure to Drug Action. The characteristic action of a drug is intimately related to its chemical structure. The study of the relationship between chemical structure and pharmacological action has led to the synthesis of many valuable therapeutic agents. Sometimes this relationship is a very broad one. For example, in the discussion of the chemistry of the local anesthetics, it is pointed out that, although certain basic structural features are seemingly associated with anesthetic activity, many variations of this basic structure can be made without a loss of characteristic pharmacological properties. The activity of other drugs is lost if the slightest change is made in the configuration of the molecule. In some instances specificity of structure is of such fundamental importance that optical isomers differ in their pharmacological actions. The ergot alkaloids well illustrate this fact. There are many compounds which have multiple actions, and changes in the molecular configuration may alter some of these but not others. Apparently different portions of the molecule are concerned with specific responses. The various derivatives of morphine are excellent examples.

Although it is tempting to attribute the action of a drug to a specific chemical configuration, there are many instances in which drugs of totally different chemical structure possess similar actions. This is especially true of the central nervous system depressants. A comparison of the structures of paraldehyde and barbital would hardly lead one to believe that their pharmacological properties are in many ways similar.

ABSORPTION, DISTRIBUTION, FATE AND EXCRETION OF DRUGS

Absorption. It is of practical importance to know the manner in which individual drugs are absorbed. In many instances the question of absorption influences the route by which a drug is administered. The rate at which a therapeutic agent gains access to the circulation largely determines the latent period between administration and onset of action. The speed of absorption is also a factor in determining dosage. Following are the more important factors which influence the absorption of drugs.

I. *Route of Administration.* Of all factors which influence the absorption of drugs, the route of administration is the most important. Often there is a choice in the route by which a therapeutic agent may be given, and a knowledge of the advantages and disadvantages of the different methods of administration is then of primary importance. The relative merits of the common routes of drug administration may be briefly discussed.

1. *Oral.* The oral route is the most ancient method of drug administration. It is also the safest, most convenient and economical. Drugs given by mouth are for the most part absorbed by the intestinal mucosa, and usually absorption is almost complete by the time the colon is reached. Seldom does an appreciable

portion reach the circulation through the stomach. There are, however, several disadvantages to the oral ingestion of drugs. Irritating substances cannot be given by mouth for they may cause emesis. Also it is not feasible to give treatment by this route to a patient who is vomiting or moribund. Many drugs are destroyed by the action of the digestive ferments before they can be absorbed. Lastly, intestinal absorption may at times be somewhat irregular due to the influence of other substances in the gastro-intestinal tract, variations in the emptying time of the stomach, the pH of the intestinal contents, etc.

2. *Injection.* Many drugs are given by injection. The injection of medicinals has certain advantages over oral administration which at times are of distinct value. In some instances this route of administration is essential in order that the drug be absorbed in active form. Absorption is usually more rapid and more predictable than when a drug is given by mouth. The effective dose can therefore be more accurately selected. In emergency therapy, parenteral administration is particularly serviceable. If a patient is unconscious, uncooperative or unable to retain anything given by mouth, parenteral therapy may become a necessity. On the other hand, there are several disadvantages to the injection of drugs. It is difficult for a patient to perform the injection himself in the event that self-medication is a necessary procedure. Strict asepsis must be maintained in order to avoid infection. An intravascular injection may occur when it is not intended. Parenteral therapy is also more expensive and less safe than oral medication, and lastly, pain may accompany the injection.

Injections may be made into any of the following sites:

(*a*) *Subcutaneous.* Subcutaneous injection is often utilized for the administration of medicinals. It can be used only for drugs which are not irritating to tissue, otherwise a slough may occur. The rate of absorption following subcutaneous injection of a drug is often sufficiently even and slow to afford a fairly sustained effect. Moreover, the rate of absorption from the subcutaneous tissue may be willfully varied by well known technics. The subcutaneous injection of a suspension of a drug in a vehicle in which it is insoluble results in a very slow rate of absorption. As an example may be cited the rate of absorption and duration of action of a suspension of insoluble protamine insulin as compared with that of soluble insulin (Figure 113). The incorporation of a vasoconstrictor agent in a solution of a drug to be injected subcutaneously also retards absorption. This technic is utilized in the combination of epinephrine with local anesthetics (page 289). Lastly, drugs in a solid pellet form may be implanted under the skin and be slowly absorbed over a period of weeks or months. Several hormones may be effectively administered in this manner (Figure 119).

(*b*) *Intramuscular.* Drugs are often injected deep into muscle tissue. From this site drugs in aqueous solution are rapidly absorbed. It is possible to dissolve or suspend drugs in oil and inject them intramuscularly. This leads to a very slow and even rate of absorption. Also irritating substances may be given which cannot be injected subcutaneously.

(*c*) *Intraperitoneal.* Drugs are occasionally injected into the peritoneal cavity. The intraperitoneal injection is seldom employed clinically but it is a common laboratory procedure. The peritoneal cavity offers a large absorbing surface from which drugs enter the circulation rapidly. However, the dangers of infection and adhesions are too great to warrant the routine use of the intraperitoneal route of injection in human beings.

(*d*) *Intravenous.* Drugs in solution can be introduced directly into the circulation, usually into a vein. In this instance the factors concerned in absorption are eliminated and the desired blood concentration of a drug is obtained with an accuracy and immediacy not possible by any other procedure. In most cases the action of the drug is manifest without delay and this is sometimes of importance in emergencies. Also certain irritating and hypertonic solutions can be given only in this manner, for the blood vessel walls are relatively insensitive and the drug, if injected slowly, is greatly diluted by the blood. For example, most of the arsphenamines can be given by no other route. In some instances, as in the production of surgical anesthesia by a barbiturate, the dose of a drug is not predetermined but rather is adjusted to the response of the patient receiving it, and intravenous therapy may then be mandatory in order that the response can be quickly evaluated. On the other hand, there are many dangers which attend intravenous injections. Unfavorable reactions are more prone to occur than when any other route is used. Once the drug is injected there is no retreat, whereas when subcutaneous administration is employed, absorption can be stopped by occluding the venous return from the area of injection. Repeated intravenous injections are dependent upon the patency of veins. Unless specifically indicated, drugs should never be given directly into the blood stream.

(*e*) *Intrathecal.* Certain drugs are injected directly into the subarachnoid space. In such instances, the local actions on the meninges or cerebrospinal axis are desired.

3. *Inhalation.* Gaseous and volatile drugs may be inhaled and absorbed through the pulmonary endothelium or mucous membranes of the respiratory tract and in this way gain rapid access to the circulation. The principles governing absorption and excretion of gases and vapors are discussed under the volatile anesthetics (page 67).

4. *Mucous Membranes.* Absorption of drugs takes place readily through many of the mucous membranes of the body other than that of the alimentary canal, and the more accessible ones are often employed for this purpose. Certain drugs can reach the circulation through the mucous membranes of the rectum, vagina, urethra, conjunctiva, nose and oropharynx. In many instances drugs are applied at these sites for their local action, but on occasion it is the systemic effect which is desired.

5. *Skin.* Few drugs can readily penetrate the intact skin. There are two available procedures, however, by which cutaneous absorption may be greatly increased. Drugs in suitable fatty vehicles can be rubbed into the epidermis and in this manner penetrate into the subcutaneous tissue through the cutaneous glands. This method of administration is known as *inunction.* Drugs which ionize can be made to migrate through the epidermis by means of a galvanic current, a procedure known as *iontophoresis.*

II. *Solubility.* Absorption is dependent upon drug solubility. This does not mean, however, that at the time of administration a drug must be in solution in order that it reach the circulation. Local conditions at the site of absorption alter solubility. Protamine zinc insulin is injected as an insoluble suspension; but in the subcutaneous tissue, solution is slowly effected and absorption proceeds over a long period of time. If calcium salts are given orally, there is little choice between the insoluble carbonate or the soluble chloride for the reactions taking place in the gastro-intestinal tract determine the final composition of the calcium salt. On the other hand, there are certain compounds which are so insoluble and chemically unreactive that they cannot be absorbed. Although the barium ion is highly toxic, large amounts of the insoluble barium sulfate can be given orally with the assurance that no absorption will take place.

III. *Physical State.* The physical state of a drug affects the rate of its absorption. Colloids are more slowly absorbed than crystalloids. Fat-soluble substances reach the circulation more slowly than water-soluble drugs. A drug is more readily absorbed when given in solution than when administered as a dry powder.

IV. *Concentration.* The concentration of a drug influences its rate of absorption. The injection or ingestion of drugs in concentrated solutions usually leads to more rapid absorption than the administration of the same amount in a more dilute form.

V. *Absorbing Surface.* Obviously the extent of the area over which a drug is spread greatly influences the rate of absorption. The large surface of the peritoneal cavity is one of the reasons why intraperitoneal injection results in such rapid absorption. The same is true of the pulmonary endothelium. Drugs are rapidly absorbed from intramuscular sites due to spread of the injected solution along fascial planes.

VI. *Circulation.* The vascularity of the site from which a drug is being absorbed is a major factor influencing the rate of absorption. The circulatory factor can be controlled, often to advantage. For example, it is desirable to keep local anesthetics at the site of injection for the local rather than the systemic action of these compounds is sought. Therefore, as mentioned above, epinephrine is incorporated in solutions of local anesthetics in order to produce vasoconstriction and thus reduce the rate of transfer into the circulation. Conversely, hyperemia enhances the absorption of drugs. Absorption from subcutaneous tissue can be speeded by massage sufficiently vigorous to cause hyperemia. An inadequate systemic circulation greatly retards absorption and intravenous therapy may then be required.

Distribution and Fate. Drugs, as a rule, are generally distributed throughout the body in the medium of the body fluids. Certain agents, however, show definite affinities for particular tissues and accumulate there in high concentrations. This does not necessarily mean that the particular tissue responding to a drug will contain a higher concentration of that drug than do other portions of the body. Often drugs may be selectively distributed in a particular fluid compartment of the body. The bromide ion, for example, remains extracellular in distribution. Many drugs, on the other hand, penetrate cells. Urea and sulfanilamide are outstanding examples of drugs which are distributed throughout all the body fluids.

Often active agents are stored in particular tissues and then slowly released to other organs. For example, large amounts of vitamin A may be retained in the liver. Lead is precipitated in bone, and the element may be stored in the skeletal structure for months after exposure.

Drugs are detoxified or inactivated in the body by a variety of mechanisms. Many are *oxidized.* The action of epinephrine, for example, is of short duration because the compound is readily converted to an inactive oxidation product. Such drugs as acetylcholine and local anesthetics are inactivated by *hydrolysis.* Other substances may be *reduced. Conjugation* is the mechanism for the detoxification of many drugs. For example, phenol is conjugated with glycuronic and sulfuric acids before excretion. There are many drugs which resist destruction in the body and are active until they are eliminated through the various channels of excretion.

Often a particular organ is responsible for the detoxification of a drug. Knowledge of this is of practical importance for, if the function of that organ is impaired, detoxification does not proceed in a normal manner and the degree or duration of activity of the drug involved may be different from that desired. To cite a specific example, certain ultrashort-acting barbiturates used intravenously as general anesthetics for minor operations are destroyed by the liver. If hepatic function is seriously impaired, the duration of anesthesia may be abnormally prolonged.

Excretion. Each drug is excreted in a characteristic manner. It is often of considerable importance to know the route and rate of excretion of a drug. Certain therapeutic agents may be removed from the body only by a single obligatory channel. Others may be eliminated by a number of routes. As has already been stated, a drug may be excreted unchanged, or in the form of some type of conjugation or breakdown product. The most important organs for the excretion of drugs are the kidneys, colon and lungs. All drugs which can traverse the capillary membrane appear in the urine, for few substances are completely reabsorbed by the renal tubules. However, in some instances the renal route of excretion is relatively unimportant. Many of the heavy metals are eliminated in part through the large bowel. Other agents may be excreted in the bile and in this way gain access to the feces. There are a few instances in which drugs excreted by the bile are reabsorbed by the intestines in an active form and thus their duration of action is greatly prolonged. The gases are almost entirely excreted by the lungs. Drugs can appear in any of the secretions of the body. Many substances are detectable in the saliva, and heavy metals may be present in this fluid in sufficient concentration to cause a metallic taste and induce ptyalism and gingivitis. During lactation certain drugs gain access to the milk. Sweat may also contain appreciable amounts of many drugs and if these substances are irritating, skin eruptions may occur from excretion by this route. Drugs have also been detected in the lacrimal secretion. Lastly, most drugs cross the placental barrier and gain access to the fetal circulation. For example, the use of central nervous system depressants, especially morphine, during labor may delay the onset of spontaneous respiration in the new-born infant.

Drugs are concentrated at the site of excretion and therefore many of the symptoms of poisoning are referable to the organs of elimination. In cases of poisoning by mercury, severe renal damage and colitis occur due to the excretion of the metal by the kidneys and colon. It is of prime importance, therefore, to protect the organs of excretion.

A careful therapeutist never administers a potentially toxic drug unless the organ essential for its excretion is functioning properly. For example, certain organic mercury compounds are potent diuretics. They are not to be given, however, unless renal function is adequate.

FACTORS MODIFYING DRUG ACTION

Many factors modify the actions of drugs and must be taken into account in the therapeutic use of medicinal agents.

I. Dose. Obviously the dose of a drug greatly influences its actions. The amount of a drug which causes untoward symptoms in the average individual is known as the *toxic dose;* the amount which kills, the *fatal dose*. The *minimal lethal dose* (M.L.D.), as ascertained experimentally on animals under controlled conditions, represents the amount of a drug which is fatal to 50 per cent of the animals. The *minimal dose* of a substance is the smallest amount which has therapeutic effects; the *maximal dose*, the largest amount that can be tolerated without toxic symptoms. Somewhere between the minimal and maximal doses of a drug lies the optimal or *therapeutic dose*. The figure obtained by dividing the M.L.D.

by the therapeutic dose is known as the *therapeutic ratio.* Obviously the higher this ratio, the safer is the drug to use.

Certain drugs have a biphasic action, that is, at two different dose levels they exert different therapeutic effects. Atropine is a striking example. Small amounts stimulate the vagus centrally and slow the heart rate, whereas a larger dose frees the heart from vagal inhibition and thus speeds the cardiac rate.

The therapeutic dose of a drug is influenced by many factors which are always considered before a drug is prescribed.

(*a*) *Age.* As a rule, children are more sensitive to drugs than are adults, and there are certain agents to which very young individuals are abnormally susceptible. For example, infants are markedly sensitive to central nervous system depressants, especially morphine. Several formulas are available for calculating doses for children. The three best known are the following:

Clark's rule: $\dfrac{\text{weight of child}}{150} \times \text{adult dose}$

Young's rule: $\dfrac{\text{age of child}}{\text{age} + 12} \times \text{adult dose}$

Cowling's rule: $\dfrac{\text{age of child at next birthday}}{24} \times \text{adult dose}$

Clark's rule is based on weight in pounds alone, the other two on age alone. Other rules combine both factors. All apply fairly well to children younger than 10 years of age. Clark's rule is probably the most serviceable. Doses for *infants* should be learned as such and not calculated by formula.

(*b*) *Body Weight.* The ratio between body weight and the amount of drug given determines the concentration which can be attained in the body. Therefore the average dose of a drug should be suitably changed when one is prescribing for an abnormally light or heavy individual.

(*c*) *Sex.* Women are more susceptible to the action of certain compounds than are men and in some instances this difference in responsiveness is sufficient to demand reduction in dosage. During pregnancy, for example, caution is necessary in the administration of drugs affecting the uterus.

(*d*) *Time of Administration.* The time at which a drug is administered sometimes influences dosage. This is especially true for oral therapy in relation to meals. Absorption proceeds more rapidly if the stomach and upper portion of the intestinal tract are free of food and an amount of drug which is active before may be ineffective if given after a meal. On the other hand, in the case of irritating drugs, much larger amounts can be tolerated if food is in the stomach.

(*e*) *Route of Administration.* Inasmuch as rate and extent of absorption differ with the route of administration, dosage must be adjusted to take this factor into account. The intravenous dose of a drug is often somewhat smaller than the subcutaneous, and this in turn is usually smaller than the oral.

(*f*) *Rate of Excretion.* If chronic medication is necessary, the rate of excretion or destruction of a drug is a necessary consideration in determining dosage. If a drug is repeatedly given and absorbed at a rate more rapid than it can be destroyed or excreted, the concentration in the body will rise and toxic symptoms will occur. This is known as *cumulative action* (Figure 1). Often it is desirable to maintain an even concentration of drug in the body in order to obtain a constant level of therapeutic effect. Once this level is attained, the so-called "*maintenance dose*" can be determined, that is, the daily dose of drug which balances the rate of elimination and destruction.

(*g*) *Drug Combinations.* When drugs having the same type of action are given in combination, the average dose of each should be reduced. Certain terms are used to describe the various ways in which drugs may act together. When the combined action of two drugs administered at the same time is equal to the algebraic sum of their individual effects the response is known as *summation*. Summation can be negative or positive. Negative summation is also termed *antagonism*. The stimulants and depressants of the central nervous system are outstanding examples of antagonistic groups of drugs. Positive summation is known as *synergism*. Most drugs producing the same type of response are synergistic when prescribed together. It is sometimes advantageous to prescribe two synergistic drugs rather than a single agent. By this procedure, inasmuch as only one-half of the therapeutic dose of each is employed, it may be possible to obtain a greater margin of safety if the toxic effects of the individual components are exerted on different physiological systems. Another advantage of drug combinations is that

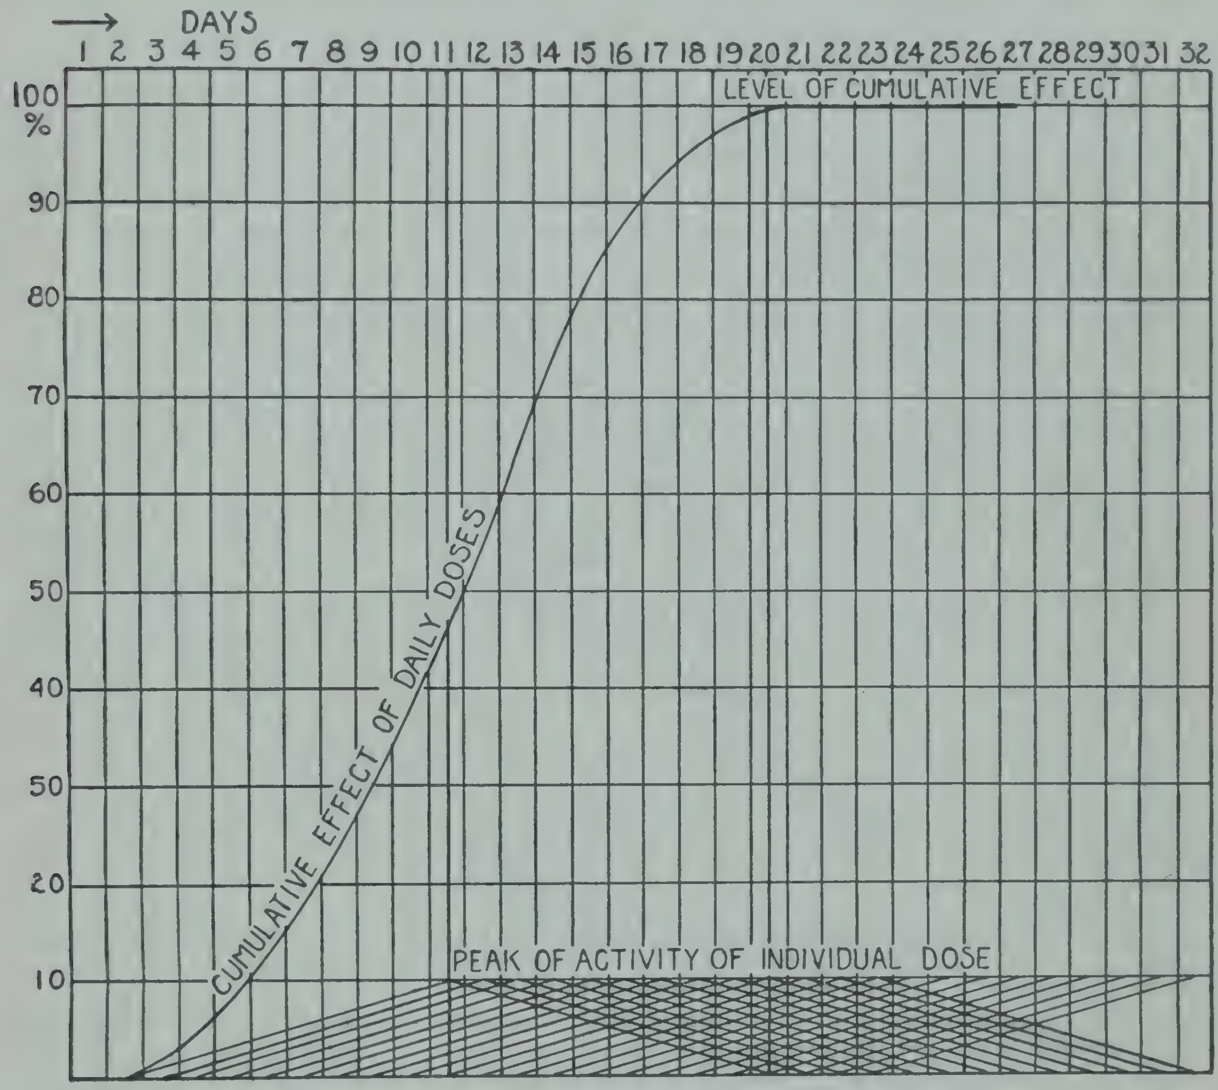

Figure 1. *Cumulative drug action.*

Schematic illustration of the effects of daily doses of desiccated thyroid, a drug which characteristically exhibits cumulative action. The effect of a single dose is not manifest until after 24 hours and does not reach its peak until 10 days later. For the sake of simplification it is assumed that the action of the drug disappears within 10 days and that the individual daily doses are merely additive. Therefore the plateau level of cumulative effect will not be reached until about the 20th day, and the ultimate effect of a given dose level cannot be determined in less time. (After *Therapeutic Notes*. Courtesy of Parke, Davis & Co.)

drugs which produce the same end-result may have entirely different mechanisms of action and in this way combine very effectively. Also two drugs having the same therapeutic effect may differ with respect to the rapidity of onset and duration of action. For example, if one drug has a rapid onset but short duration of action and another has a slow onset and prolonged duration of action, their synergistic action will be characterized by a rapid onset and long duration (Figure 2).

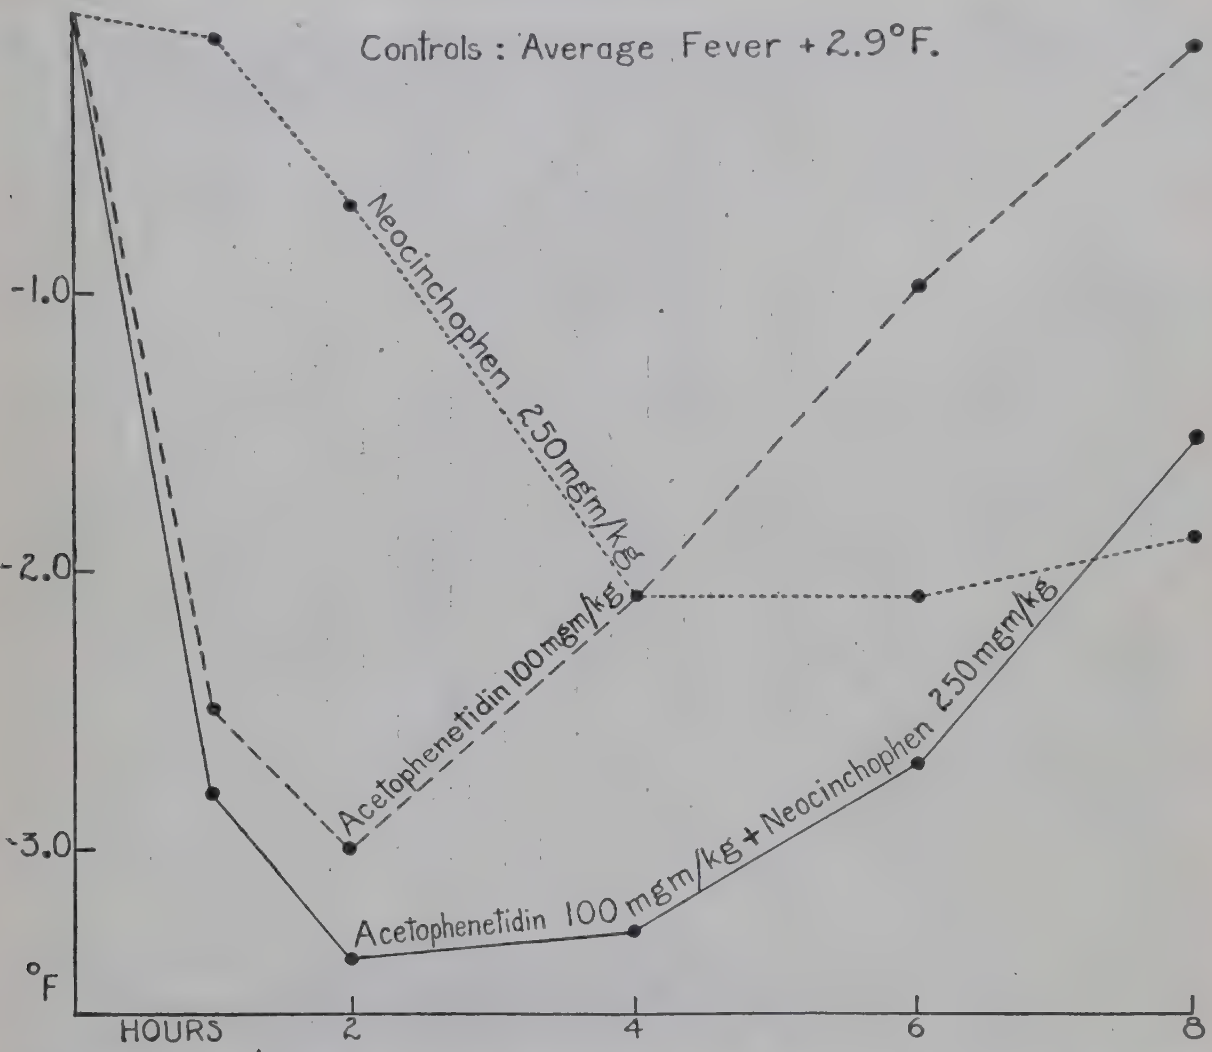

FIGURE 2. *Antipyretic experiment illustrating the phenomenon of positive summation (synergism).*

Observations were made on rats fevered by the subcutaneous injection of yeast suspension 14 hours prior to the administration of the antipyretic drugs. The latter were administered in an aqueous suspension by stomach tube. The antipyretic effect is measured by calculating the difference between the rectal temperatures of fevered control and treated experimental animals. Acetophenetidin is a powerful antipyretic with rapid onset and short duration of action. Neocinchophen is slowly absorbed and its action is less rapid in onset and longer in duration. When acetophenetidin and neocinchophen are given together, positive summation is evident in the rapid onset and prolonged duration of action, the antipyretic effect at any point being approximately the sum of the effects of the individual drugs.

There are instances in which the combined action of two drugs is greater than that which can be anticipated from the sum of their individual actions. This is known as *potentiation*. For example, the administration of acid-forming saline diuretics prior to a mercurial diuretic results in a greater volume of urine than is predictable on the basis of individual effects (Figure 69).

II. Tolerance. Tolerance may be acquired for many drugs and if this occurs, the dose must be progressively increased in order to maintain a given therapeutic response. The nitrites represent a group of drugs to which tolerance develops. When prescribing nitrites for hypertension one starts with the lowest effective dose because this may shortly have to be increased as tolerance develops.

Occasionally a person is tolerant to a drug which he has never taken before. This is known as *individual tolerance*. Certain species are relatively insensitive to particular drugs. This is known as *species tolerance*. For example, rabbits show a marked species tolerance to belladonna alkaloids. Resistance to the action of certain drugs sometimes results in tolerance to chemically related compounds having a similar action. This is known as *cross tolerance*. The patient who as a result of continued use is tolerant to alcohol may also be tolerant to tribromethylalcohol (avertin), ether and related central nervous system depressants.

The continued use of some drugs may lead to *habituation*, a condition which is characterized by a psychic craving manifested when the drug is withdrawn. A large number of drugs are capable of producing habituation, and if sufficient psychic influence is brought to bear, habituation may occur to pink water. The repeated administration of certain drugs, notably morphine and related alkaloids, cocaine and alcohol, may result in *addiction*. In this instance, withdrawal results not only in psychic craving but also in a characteristic abstinence syndrome of organic origin which is manifested in distorted physiological processes. Evidently in the addicted individual the presence in the body of the addicting drug is necessary to maintain normal cellular functions. The only reliable test for addiction is withdrawal of the drug and close observation of the individual for the appearance of characteristic abstinence symptoms and signs. Tolerance to a drug need not necessarily be associated either with habituation or addiction.

III. Idiosyncrasy. *Idiosyncrasy* is an abnormal or unusual response to a drug, and may occur even to very small doses. It is one of the factors modifying drug action which usually cannot be anticipated in advance. An abnormal response may occur after a drug has been administered for the first time or it may suddenly appear during an uneventful course of chronic medication. The unusual responses associated with the use of drugs have been learned only from experience. In many cases, idiosyncrasy may manifest itself in such a subtle manner that any association of the drug with the untoward reaction may escape recognition until the drug has been in general use for many years. Such was the case with cinchophen which was employed in the treatment of gout for 17 years until it was finally appreciated that in some individuals it may cause a fatal toxic hepatitis.

Idiosyncrasy may manifest itself in many ways. A rare individual is excited rather than depressed by morphine. A therapeutic dose of aspirin in a susceptible person may cause a severe anaphylactic response. Aminopyrine may inhibit the maturation of polymorphonuclear leukocytes to such a degree that severe agranulocytosis results. Arsphenamine in isolated instances may depress all cellular elements of the bone marrow and cause an aplastic anemia.

IV. Influence of Pathological States. The actions of certain drugs are considerably modified by pathological conditions. Antipyretic agents cause a marked fall in body temperature in an individual with fever. but if the same dose is given to a person whose temperature is normal no noticeable decrease is obtained. A therapeutic dose of a diuretic drug produces only a slight augmentation in the urine flow of a normal individual but may promote the excretion of several liters of fluid in an edematous patient. An individual with hyperthyroidism is responsive to a dose of epinephrine that would scarcely affect a person with a normal metabolic rate, but on the other hand he can tolerate larger doses of morphine than can normal individuals. Conversely, the patient with myxedema may be seriously narcotized by a dose of morphine which normally is only moderately depressant. In many cases it is of utmost importance to be familiar with the unusual modifications of drug action which certain pathological conditions can produce.

V. Cumulative Action. The cumulative action of a drug may modify its effects greatly, changing a therapeutic action into a toxic one. If a drug is excreted slowly, its continuous administration may build up a sufficiently high concentration of drug in the body to produce poisoning.

CHEMICAL CLASSIFICATION OF DRUGS

From a chemical point of view, drugs may be classified in many ways. A major distinction may be made between synthetic drugs and those which occur naturally. In the past, the major advances in pharmacology were made as the properties of drugs of natural origin were studied and applied in therapy. This field has been largely exhausted, with the exception, however, of the hormones and vitamins, natural products of animal and plant origin. The study of synthetic drugs is a very young field of investigation. The recent additions to the growing list of synthetic preparations, such as cyclopropane, sulfanilamide, sulfapyridine, dilantin, stilbestrol, desoxycorticosterone, mapharsen, carbarsone, choline esters, prostigmine, synthetic morphine derivatives, etc., predict an exciting future and broadening scope for pharmacotherapeutics.

Synthetic Drugs. It is of little importance to classify synthetic drugs from a chemical point of view. They range from simple inorganic preparations to complex aliphatic and aromatic organic compounds.

Natural Drugs. Natural drugs of plant origin lend themselves more readily to chemical classification. The majority of medicinal substances obtained from plants fall into the following groups: *alkaloids, neutral principles, acids, tannins, fats, waxes, fixed oils, volatile oils, resins, oleoresins* and *balsams*. Only the first two groups require further definition and discussion.

Alkaloids. The majority of the important drugs obtained from plants are in this category. The alkaloids are basic organic compounds containing nitrogen. The alkaloids are so named because alkaloidal solutions are weakly alkaline in reaction. Alkaloids form salts with acids by addition on the nitrogen group. They have characteristic solubilities, the alkaloidal salts being soluble in water, and the free bases in organic solvents. A few alkaloids are liquid in their basic form but the great majority are solids. All are bitter to the taste. They have distinguishing names in that all end in *"ine."* Morphine and atropine may be named as outstanding examples of plant alkaloids. Many synthetic substances have the chemical characteristics of alkaloids and could be so classified.

Neutral Principles. Neutral principles, in contrast to alkaloids, are neutral in reaction. The names of the drugs in this class end in *"in."* The neutral principles have no distinguishing chemical features aside from their neutral reaction and embrace a wide variety of chemical substances. Included among the neutral principles are the *glycosides.* Glycosides are neutral principles which contain a carbohydrate molecule in conjunction with one or more other chemical bodies.

The carbohydrate molecule is not necessarily essential for the action of a glycoside and may be removed by hydrolysis to leave an active *aglycone*. Outstanding examples are the cardiac glycosides, the chemistry of which is discussed in detail under digitalis (page 501). An example of a neutral principle that is not a glycoside is picrotoxin.

PHARMACEUTICAL PREPARATIONS OF CRUDE DRUGS

It is not always feasible to isolate pure drugs from natural sources and many drugs of plant or animal origin are administered in the crude form. Crude preparations of natural drugs are often referred to as *galenicals*. This term derives its name from Galen who described methods for the preparation of many crude drugs, and it is now employed to distinguish the following classes of medicinals from those obtained by more elaborate chemical procedures:

(1) **Tinctures.** Tinctures are alcoholic or hydro-alcoholic solutions of the active principles of animal or vegetable drugs. The proportion of drug represented in the different kinds of tinctures is not uniform but varies according to the established standards for each. For potent drugs, the usual procedure is to extract by percolation 10 grams of the crude drug for each 100 cc of the final alcoholic solution.

(2) **Extracts.** Extracts are concentrated preparations of vegetable or animal drugs obtained by extracting the active constituents of the respective drugs with suitable solvents, evaporating all or nearly all of the solvent and adjusting the residual masses or powders to the prescribed standards.

(3) **Fluidextracts.** Fluidextracts are liquid preparations of vegetable drugs containing alcohol as a solvent, as a preservative or both, and made so that one cc contains the therapeutic constituents of one gram of the standard drug which it represents.

(4) **Decoctions.** Decoctions are liquid preparations prepared by extracting a crude drug with actively boiling water. One liter of a decoction is usually prepared from 50 grams of crude drug.

(5) **Infusions.** Infusions differ from decoctions in that the crude drug is extracted with water without active boiling. The water may be at any temperature depending upon the stability of the drug to heat.

In many instances crude drugs are employed after no more formal procedure than drying and pulverizing the active portion of a plant or animal tissue.

BIO-ASSAY OF DRUGS

Crude preparations of drugs often must be assayed in order to determine their drug content. In the event that the chemical composition of the active ingredient of a crude drug preparation is known, it may be possible to determine the activity by means of chemical analysis. Sometimes it suffices to determine the activity of a crude drug merely by analyzing for a particular chemical group or element. Thus the potency of *Thyroid*, U.S.P., is assayed on the basis of the iodine content of the dried gland.

Often, however, no chemical method is available to determine the pharmacodynamic activity of crude preparations and one must resort to *bio-assay*. Bio-assay is the measure of the concentration of a specific active ingredient of a crude drug, and is performed by determining the amount required to produce a definite effect on a suitable test animal or organ under standard conditions. The activity of many important therapeutic agents is standardized in this way. The usual technic is to compare the action of the drug being assayed with that of a known standard under rigidly controlled conditions. The method of bio-assay employed differs for individual drugs and is usually based upon the therapeutic action of that drug. For example, the activity of an insulin preparation is determined by its ability to lower the blood sugar in rabbits. The vitamin D activity of cod liver oil is determined by the ability of the oil to cure rickets in rats. A toxic property of the drug, however, may be used for bio-assay. Thus the potency of powdered digitalis is measured by its toxic effect on the frog heart. In one instance, a bio-assay is conducted on human beings. Because no suitable laboratory test animal is available for the assay of antianemia substances, liver and stomach preparations are tested for their potency on patients with classical pernicious anemia in relapse.

The activity of a crude drug which is bio-assayed is usually expressed in terms of *units*. Both the unit and method of assay are rigidly defined, in some instances by international committees so that universal standards exist. Official drugs have legally required methods of assay, which lead to uniformity, at least, within a given country. Unfortunately, in the case of many of the newer preparations, notably the endocrines, there is no prescribed method of assay or commonly accepted unit and the commercially available products vary considerably in strength. As a drug gains wide use, however, this condition is frequently rectified by the appointment of a suitable board or commission to solve the problem of assay and unitage.

The methods of bio-assay of individual drugs are discussed in the text as occasion arises.

OFFICIAL AND NONOFFICIAL DRUGS

Once the physician has decided upon a course of therapy for his patient, it is imperative that the patient receive exactly what has been prescribed. Drugs must therefore be of a uniform quality. The physician may readily assure himself of this by prescribing official drugs.

An *official drug* in the United States is one which is included either in the United States Pharmacopeia (U.S.P.), The National Formulary (N.F.) or The Homeopathic Pharmacopeia. Other nations have similar drug standards; the official one in the British Empire is the British Pharmacopeia (B.P.).

United States Pharmacopeia. The United States Pharmacopeia (usually designated as the U.S.P.) is a publication in which the approved therapeutic agents used in medical practice are described and defined with respect to source, chemistry, physical properties, tests for identity, tests for purity, assay, method of storage and average therapeutic dose. Most of the preparations in the U.S.P. are single drugs. In the case of those which must be compounded, instructions are given for their preparation. The object of the U.S.P. is to provide standards for drugs and medicines of therapeutic usefulness or pharmaceutic necessity. The first Pharmacopeia in the United States was published in 1820, and since that time numerous revisions have appeared. The current edition, U.S.P. XI, became official in 1936. It is the practice to revise the Pharmacopeia at 10 year intervals but, in the interim, *Supplements* are now published which include new preparations. In this manner the Pharmacopeia can be kept abreast of rapid advances in pharmacotherapeutics. Supplements to the U.S.P. XI appeared in 1937 and 1939. As an indication of the speed with which outstanding new drugs are included in the Pharmacopeia, the following agents appearing in the 1939 Supplement may be mentioned: Ascorbic Acid, Nicotinic Acid, Pentobarbital Sodium, Cyclopropane, Sulfanilamide and Thiamine Hydrochloride.

The U.S.P. is revised by a special Pharmacopeial Committee, the members of which donate their services in the interest of the important function which they serve. The Pharmacopeial Committee consists of outstanding pharmacologists, physicians and pharmacists. The general committee on revision is assisted by numerous subcommittees and advisory boards. As examples may be cited the *U.S.P. Vitamin Advisory Board,* the *U.S.P. Anti-Anemia Products Advisory Board,* the *U.S.P. Committee on Cardiac Drugs,* etc.

The drugs included in the U.S.P. are *official* by virtue of the fact that the Federal Pure Food and Drug Act designates the Pharmacopeia as one of the volumes defining the official standards of purity for drugs. Thus the physician, by prescribing official drugs, is assured of their quality and uniformity.

Patented drugs cannot be made official drugs for the reason that the patentee is the sole arbiter for the standards of the product. They cannot be included in the U.S.P. until patents expire; this explains why many outstanding therapeutic agents, as for example insulin, are not official. Neither can a drug be labeled U.S.P. which does not bear the official name of the drug.

The National Formulary. The National Formulary (usually designated as N.F.) was first published in 1888 under the name "National Formulary of Unofficial Preparations." At that time it contained only formulas for preparations of drug mixtures. Standards for those drugs included in the formulas but not listed in the U.S.P. were given. The publication became an official drug standard when so designated by the Federal Pure Food and Drug Act of 1906, after which the name was changed to *The National Formulary.* The current edition is the N.F. VI, published in 1936.

The National Formulary is published by the American Pharmaceutical Association. It is prepared by a committee consisting mainly of outstanding pharmacists. The purpose, as defined in the National Formulary, is ". . . to supply definite formulas for preparations that are sufficiently used in medical practice in the United States, or its possessions, and for which formulas are not included in the Pharmacopeia of the United States, Eleventh Revision; and to provide standards and tests for the identity, quality, and purity of the ingredients used in these formulas, and for such other medicinal materials as are frequently called for in the pharmacies of the United States for which standards are not provided in the U.S. Pharmacopeia XI, so that uniformity in the physical properties and therapeutic action of these preparations will be assured."

The N.F. supplements the U.S.P. in many important ways. The Pharmacopeia is a more valuable and critical publication in that the therapeutic worth and the toxic potentialities of a drug are considered before an agent is included. The N.F. contains drugs on the basis of demand. For example, *Cinchophen,* U.S.P. X, was deleted from the U.S.P. XI because of the propensity of the drug to damage the liver. Cinchophen is still employed, however, and in order that there may be official standards for its purity, the drug is included in N.F. VI. Likewise, many other drugs which have been deleted from the U.S.P. appear in the N.F. The National Formulary also differs from the Pharmacopeia in that it contains principally formulas of drug mixtures rather than monographs on discrete drugs. Thus the majority of the so-called *official prescriptions* are to be found in the N.F. As in the case of the Pharmacopeia, only non-patented drugs under their official titles are admitted to the N.F.

The Epitome of the U.S.P. and N.F. The physician has little need for the detailed information contained in the U.S.P. and N.F. but rather he is chiefly concerned with knowing which drugs are official and a few pertinent facts concerning their physical and chemical properties. The American Medical Association publishes a small, inexpensive and valuable volume known as the *"Epitome of the United States Pharmacopeia and National Formulary."* In it are given the titles of the drugs included in each of the official publications and such facts as are useful to physicians.

Official Nomenclature. Drugs included in the U.S.P. and N.F. bear official titles. Many drugs have one or more official synonyms. Many pharmaceutical concerns, however, prefer to market their official drugs under trade names rather than official names. This fact immediately necessitates wide advertisement of the trade name of the drug to the medical profession so that the drug will be purchased by its trade name rather than by its official title. Naturally, advertising incurs an expense which must be borne by the person who eventually buys the trade-marked product. A drug sold under a trade name is usually considerably more expensive than the identical substance bearing only an official title. Even when a physician unwittingly prescribes an official drug by its trade name, the pharmacist is obligated to fill the prescription with the brand of drug ordered, thus entailing unnecessary expense for the patient. There is little reason for the physician to be unaware of the official nature of drugs marketed under trade names for the official nomenclature must by law be stated on the label.

Nonofficial Drugs. Much of the current research in the development of therapeutic agents is performed in the laboratories of or subsidized by reputable drug firms. In legitimate return for his investment, the manufacturer can patent his product and enjoy the exclusive rights of its manufacture and sale. Many drug houses release a new therapeutic agent only after it has received a thorough experimental study and clinical trial, announce the chemical composition of the agent and are circumspect in regard to the claims that are made for the drug. Not all patented drugs, however, are promoted in this manner. Some are marketed with little experimental evidence of their effectiveness and unwarranted and unsupported claims are made for them.

The physician's concern is not with the possibility of overlooking a significant new therapeutic advance. Rather, his problem is to differentiate between the extravagant and truthful claims in the advertising material with which he is deluged. This can be accomplished by a meticulous time-consuming study of the literature pertaining to the pharmacological actions of and therapeutic results obtained with the drug in question. The validity of the conclusion depends upon the ability of the physician critically to select and to evaluate the cogent evidence for and against the new therapeutic agent. An alternative course is to depend upon the judgment of the *Council on Pharmacy and Chemistry* of the American Medical Association.

New and Nonofficial Remedies. The Council on Pharmacy and Chemistry (subsequently referred to as the *Council*) is composed of a group of outstanding physicians and scientists. The Council publishes the book entitled *New and Nonofficial Remedies* (*N.N.R.*). Included in N.N.R. are descriptions of proprietary articles which have been *accepted as conforming to the rules of the Council,* such simple non-proprietary and nonofficial substances as seem of sufficient importance to warrant their inclusion, and simple pharmaceutical preparations, the inclusion of which is believed to give useful information to physicians. The *rules of the Council* are designed primarily to protect the medical profession and the public against fraud, undesirable secrecy and objectionable advertising in connection with proprietary medicinal articles. The rules can be found in the introduction to N.N.R. The descriptions of drugs include chemical and physical properties, tests for identity and purity, dosage, preparations, actions and uses.

There is no compulsion for manufacturers to submit their drugs to the Council for inclusion in N.N.R. However, the opinions of the Council are so widely accepted by the members of the medical profession that many drug distributors attempt to obtain for their proprietary products the seal of acceptance of the Council on Pharmacy and Chemistry of the American Medical Association. Thus there are few proprietary drugs of outstanding value which have not been submitted to the Council. There are many reasons why a drug may be rejected by the Council. Usually it is because it has little therapeutic worth. Occasionally however, a drug of genuine value is rejected because of the name given to it, the claims made for it, or the manner in which it is advertised. Usually these difficulties are ironed out by consultation between the distributor and the Council, and it is only an occasional proprietary drug of proved worth which is not included in N.N.R.

New and Nonofficial Remedies is published annually, shortly after the beginning of the year, and includes preparations accepted up to the beginning of that year. A supplement dealing with preparations accepted during the following six months is also released. The N.N.R. is sold by the American Medical Association at a nominal price. Throughout the year, notification of acceptance or nonacceptance of individual drugs is published in the *Journal of the American Medical Association*. Thus little time need elapse before an outstanding new drug is accepted by the Council. The *Reports of the Council,* usually released at the time a drug is accepted or rejected, are valuable sources of current pharmacological information. They are written either by Council members or by outstanding consultants who are specialists in the field of medicine to which the drug under consideration pertains.

The protection that the Council affords the physician cannot be overestimated. At the price of only a slight delay, he can employ proprietary drugs with the assurance that they have been approved by specialists best equipped to pass judgment on a particular therapeutic agent. By prescribing Council-accepted drugs, not only does the physician know that he is using an agent which meets the claims of the manufacturers, but also that the drug has been carefully scrutinized in regard to its potential toxic effects. It is only the research pharmacologist in conjunction with the clinical specialist who should be entrusted with the evaluation of new drugs, and for the average physician to relegate this responsibility to others, as he does when he gives preference to Council-accepted preparations, is not a discredit to his pioneering spirit but rather a favorable reflection on his scientific judgment.

THE FEDERAL FOOD, DRUG AND COSMETIC ACT

The current Federal Food, Drug and Cosmetic Act became law in 1938. It replaced the original act passed in 1906. The act is designed for the protection of public health, but it also serves to protect the physician from unethical practices of irresponsible drug manufacturers. Enforcement of the law is entrusted to the

Food and Drug Administration of the Department of Agriculture. The physician should be familiar with the provisions of this act and assist in every way possible in its enforcement. Features of the act of particular interest to the medical profession have been summarized by Klumpp (1939). Following are some of its major provisions pertaining to drugs:

(1) It brings under governmental control drugs used in the diagnosis of disease and drugs intended to affect the structure or any function of the body.

(2) Prohibits traffic in drugs and devices which are dangerous to health under conditions of use prescribed in the labeling.

(3) Prohibits traffic in new drugs unless such drugs have been adequately tested to show that they are safe for use under the conditions of use prescribed in their labeling; authorizes exemption from this requirement of drugs intended solely for investigational use by qualified scientific experts.

(4) Requires drugs intended for use by man to bear labels warning against habit formation if they contain any of a list of narcotic or hypnotic habit-forming substances, or any derivative of any such substance which possesses the same properties.

(5) Requires the labels of nonofficial drugs to list the names of the active ingredients, and in addition to show the quantity or proportion of certain specified ingredients.

(6) Requires the labeling of drugs and devices to bear warnings against use in those pathological conditions or by children when such use may be dangerous to health, or against unsafe dosage or methods or duration of administration or application, in such manner and form as are necessary for the protection of the user.

(7) Requires labels of official drugs to reveal any differences of strength, quality or purity from the official standards.

(8) Requires official drugs to be packaged and labeled as prescribed by the Pharmacopeia and National Formulary.

(9) Declares nonofficial drugs illegal if the standard of strength thereof differs from, or the purity or quality falls below, the standard claimed.

(10) Requires that antiseptics possess germicidal power.

The above provisions do not apply to physicians' prescriptions. The law assists the physician in that it rigidly controls the standards, purity and composition of drugs and drug mixtures. In the last analysis, the law is designed to protect the layman who insists in indulging in self-medication, but it cannot compare in its results with the protection afforded by proper medical care on the part of a physician.

GENERAL PRINCIPLES OF TOXICOLOGY

Toxicology is the science of poisons. The subject matter of this broad branch of pharmacology includes the origin, chemical properties, toxic actions and detection of poisons, and the treatment of intoxications produced by them. A poison is difficult to define. Even such a benign substance as water can be toxic if administered in sufficiently large amounts. Many definitions, therefore, limit the term poison to those substances which cause toxic effects in amounts under 50 grams, but this is quite arbitrary. Also only substances acting chemically on body tissues are usually considered poisons. Ground glass, for example, would be excluded from consideration as a poison by this restriction. Lastly, in order that a drug may be classed as a poison, the toxic action must represent its usual effect. A person may be allergic to a certain protein, yet this protein is toxic only under special circumstances and therefore cannot be considered as a poison. The following definition cited by Peterson, Haines and Webster (1923) takes all these factors into account: "*A poison is a substance, which, when introduced into the body in relatively small quantity and acting chemically, is capable of producing death or serious injury to health in the case of an ordinary individual in average health.*"

It is evident that few drugs employed in therapeutics are excluded even by the most rigid interpretation of the above definition. All drugs are potential poisons and the separation of their pharmacological and toxicological properties is often difficult and sometimes impossible or unprofitable. Therefore at this time only the broad principles of toxicology are discussed. The symptoms and treatment of poisoning by specific agents appear under the discussion of the individual drugs.

The physician is not interested in all aspects of toxicology. The detection of poisons is an intricate procedure which demands specialized training. Rather the practitioner devotes his attention to the symptoms, diagnosis and treatment of poisoning. However, in the event of poisoning, the physician is usually one of the first present and therefore certain obligations and duties fall upon him.

Duties of the Physician in Poisoning Cases. If the circumstances surrounding a case of poisoning are at all suspicious, the physician has a duty to the State as well as to the patient. He should therefore preserve any evidence which may prove of special value. This includes any vomitus, urine or stool that is passed, and any food or medicine that could possibly have contributed to the symptoms. The specimens should be stored in clean glass jars and sealed in such a way as to preclude the possibility of tampering. The samples should then be transferred to the proper authority for subsequent analysis. At the first available opportunity, the physician should make accurate written notes of the important aspects of the case. This may be of great value if the case should become medico-legal and testimony in court is necessary. Also the physician's accurate observations of the patient are of great assistance to the toxicologist, whose task is simplified if the symptoms were sufficiently characteristic to point to a specific drug or one of a group as the offending agent.

The physician should never sign a death certificate or allow the release of the body to the undertaker if he is suspicious that the patient may have succumbed from poisoning, but should communicate with the coroner or medical examiner. If the patient is still living, and has been the victim of malicious poisoning, he should be removed from possible danger by transferring him to a hospital. The legal duties of the physician have then been fulfilled with the exception of any help which he may render the proper authorities on the basis of his contacts with the case.

Occurrence of Poisoning. Poisoning may be accidental, suicidal or criminal. Accidental poisonings are common in children. A young child especially conveys most objects to his mouth. The tragedy of the high incidence of poisonings in childhood is that most of them could be avoided. Parents cannot be too strongly urged to keep medicinals out of the reach of children. Neither should poisonous vermicides or insecticides be placed in the home. Many common household articles which are poisonous should be made unavailable to children. Accidental poisoning among adults is not uncommon and usually results from attempts at self-medication or from mistaking one drug for another.

Suicide by drugs and noxious gases is also common. Drugs have definite waves of popularity as suicidal agents. Barbiturates and carbon monoxide are two that are often employed. Every physician should be able to treat poisoning caused by agents commonly used for suicidal purposes.

Criminal poisoning was at one time much more prevalent than at present. The rapid strides made in the science of toxicology have largely discouraged this form of criminal attack.

Diagnosis of Poisoning. The diagnosis of poisoning is not simple. Although the toxic actions of most drugs are characteristic, there is scarcely a syndrome produced by a toxic agent which cannot be simulated by disease. For example, symptoms caused by the central nervous system stimulants may be mistaken for epilepsy, tetanus, hypoglycemic convulsions, etc.; those by the central nervous system depressants, for cerebral vascular accidents, uremic coma, brain tumor, etc. Special difficulty is experienced in diagnosing chronic poisoning. A significantly high percentage of individuals admitted to psychopathic institutions are found to be suffering from chronic bromide intoxication which often simulates a neuropsychiatric disorder. The true etiology of the symptoms of chronic acetanilid poisoning may escape all but the most astute observers. The more uncommon types of industrial poisoning may go undiagnosed until irreparable injury has been suffered by the patient.

There are a number of helpful signs and symptoms which assist in the detection of acute poisoning. The onset of illness is usually sudden and occurs in an individual who has been previously well. However, there are diseases which develop rapidly and a number of drugs which have a slow onset of action. Another factor suggestive of poisoning is that the symptoms usually follow the taking of food, drink or medicine. In the event that several individuals suffer from similar symptoms after partaking of the same food, the likelihood of a poisonous substance being the cause is great. Most often, however, it is the characteristic actions of a drug which are recognized. Many leave a tell-tale odor. Irritant drugs may produce their effects on the mucous membrane of the mouth and throat. Such drugs as atropine and morphine have characteristic actions on the pupil. The typical appearance of a person poisoned by carbon monoxide and the circumstances under which he is discovered immediately lead to an almost certain diagnosis. When all the factors of a case are considered the diagnosis of acute poisoning can usually be made with certainty. As a final check there are often simple chemical tests which can be performed rapidly in order to confirm the clinical diagnosis.

The diagnosis of chronic poisoning is often difficult. At times the symptoms and signs are not sufficiently specific to point to the toxic agent, and in many cases laboratory procedures are essential. In others, painstaking probing of the patient's history, habits, daily activities, working conditions, etc., may lead to a solution of the problem.

Treatment of Acute Poisoning. In the following discussion, only the general principles of the treatment of acute poisoning are discussed. The particular procedures employed in combating the effects of specific agents are presented under the individual drugs. Much can be learned from a general discussion, however, for in a number of instances it is not necessary to identify the specific substance causing symptoms in order rationally to treat a case of poisoning. Rather most emergency therapy is symptomatic. Success is often dependent upon celerity, and valuable time cannot be wasted in a positive identification of the specific cause of the patient's illness. The usual steps taken are (1) the removal of the poison from the body, (2) the administration of antidotes, and (3) supportive or symptomatic therapy. Although these procedures are listed in the order in which they are usually performed, there are times when it is necessary to give supportive or antidotal therapy before steps are taken for the removal of the poison.

Removal of Poison from Body. Poisons which have been applied externally are best removed by copious washing with water. If the toxic agent is a strong acid or base it is theoretically advantageous to wash with a dilute neutralizing agent. In actual practice, however, the loss of time in procuring the more suitable wash nullifies any theoretical advantage. In case the toxic agent is not water-soluble, a suitable organic solvent should be employed. For example phenol is best removed with alcohol or castor oil.

The removal of a poison that has been ingested orally is more difficult. A great deal of emphasis has been placed upon the use of *emetics*. Actually it is only in rare cases that such drugs are of any value. Emetics act by stimulating the medulla, either directly or reflexly by irritation of the walls of the stomach (page 812). Such medullary stimulation is followed by some degree of depression. Also, if the patient has ingested a central nervous system depressant, it is possible that either type of emetic may prove inactive. The administration of a medullary stimulant to an individual suffering from the effects of a central nervous system stimulant is likely to increase the severity of symptoms. A corrosive poison is in itself emetic. In the occasional instance in which the employment of an emetic is justified, the most useful drug is apomorphine. Apomorphine can be given parenterally, acts rapidly by a direct effect on the medulla, and is more certain in action than the gastric irritants which reflexly stimulate vomiting (page 813). Mustard is a common household article which has an emetic action and can be employed in an emergency (page 814).

Gastric lavage is a much more certain and thorough method for evacuating the stomach. The danger of perforating the esophagus or stomach in cases of corrosive poisoning or precipitating a convulsion in strychnine poisoning are the two major contraindications to this procedure. Once the stomach tube has been passed, the gastric contents can be evacuated and the stomach repeatedly washed in order to remove all traces of poison. Chemical antidotes may be employed in order to increase the efficiency of the lavage. Finally, after the stomach has been thoroughly cleansed and emptied, one can administer through the stomach tube a generous dose of a saline cathartic. This will speed the passage of any drug which has passed through the pyloric sphincter and thus diminish the extent of its absorption in the intestinal tract.

In using the stomach tube, care should be taken to prevent the aspiration into the lungs of gastric contents or lavage fluid. The head should be low and turned to the side when aspirating or siphoning material from the stomach. Also, when removing the tube from the stomach, it should be firmly pinched in order to forestall the possibility of fluid leaking and gaining access to the lungs as the opening passes the pharynx.

Inasmuch as many drugs are concentrated at the site of excretion, attention should be directed toward the organs for elimination of a particular poison. Although in most instances it is not possible markedly to hasten the excretion of a drug, precautions may be taken to protect the excretory organs. Large amounts of fluid should be given to dilute nephrotoxic poisons in the renal tubule. In a few instances the renal excretion of a drug can be enhanced by specific procedures. For example, in bromide poisoning, the excretion of bromide can be greatly hastened by the administration of chlorides. Water diuresis augments the excretion of sulfanilamide. It is only in isolated cases, however, that the renal excretion of a drug can be appreciably speeded. Volatile substances which are excreted by the lungs can be more rapidly eliminated by stimulating respiration, and for this purpose the inhalation of carbon dioxide is often employed. If the poison is excreted by the intestinal mucosa, care should be taken to avoid constipation.

Antidotes. Antidotes can be divided into two main classes, *chemical* and *physiological.* A chemical antidote is one which inactivates a poison by chemical means. The site of action of most chemical antidotes is the stomach where they precipitate, oxidize or otherwise render a drug innocuous or incapable of absorption. Usually the combination of antidote and drug is not a stable one and the gastric contents should be removed by lavage. A few chemical antidotes are given parenterally and can inactivate poisons that have already been absorbed. Outstanding examples are the use of sodium formaldehyde sulfoxylate in the treatment of mercury poisoning (page 734) and the employment of nitrites and thiosulfates for the treatment of cyanide poisoning (page 701). A physiological antidote is one which combats the physiological effects of a poison. An outstanding example is the use of stimulants of the central nervous system to overcome the effects of central depressants. Often one does not have a choice of antidotes but must resort to the one most readily available. The common household articles which are effective are milk and egg white for poisoning by heavy metals, flour and starch as colloidal substances to prevent absorption of all types of poisons, starch being particularly effective against iodine, and strong tea and diluted tincture of iodine for the precipitation of alkaloids. The specific antidotes employed against individual poisons are discussed throughout the text.

Supportive Therapy. Adequate supportive therapy is as important in the treatment of poisoning as is the administration of specific antidotes. It is important to maintain the vital processes of the body at the highest possible functional level in order to facilitate the detoxication and excretion of the poison and enable the patient to recover from the injurious effects. The patient should be kept in bed and warm, under competent surveillance, and particular attention should be paid to the respiration, circulation and organs of excretion and detoxication. This often necessitates hospitalization. Shock is a common symptom of acute poisoning and the routine of shock therapy (page 587) is often employed. The many drugs and the manner in which they are used to combat poisoning are discussed in the text.

SECTION II

CENTRAL NERVOUS SYSTEM DEPRESSANTS

Drugs acting upon the central nervous system may be grouped into *stimulants* and *depressants.* The depressants are by far the more important, and represent the most widely used of all therapeutic agents. For convenience, central nervous system depressants may be divided arbitrarily into several categories. A simple and useful classification is as follows:

1. *General anesthetics,* such as ether, cyclopropane, ethylene.
2. *Sedative-hypnotic-soporific* drugs, such as the barbiturates, chloral hydrate, bromides.
3. *Narcotics,* such as morphine and related alkaloids.
4. *Analgesics* and *antipyretics,* such as the salicylates, acetanilid, aminopyrine.

It is evident that there is considerable overlapping in this classification. For example, any of the sedatives can be given in sufficient amount to cause anesthesia. Even such a mild sedative as bromide may cause profound coma if given in sufficiently large doses. On the other hand, the general anesthetics produce analgesia. From a therapeutic standpoint, however, the groups mentioned are fairly distinct.

The terms previously used may be more definitely delimited by the definitions which follow:

Anesthesia. Literally, this word means "without sensation." General anesthesia includes the loss not only of all modalities of sensation but also of consciousness. *Surgical anesthesia* is sufficiently deep to allow surgical operations to be performed. *Basal anesthesia* is a lighter degree of anesthesia obtained by the giving of sufficient preanesthetic medication. It allows the patient to be brought to the operating room in an unconscious state, yet not sufficiently depressed for surgical procedures. Tribromethanol is a good example of a basal anesthetic agent.

Narcosis. This term is variously defined. As used here, narcosis refers to a condition of analgesia accompanied by deep sleep or stupor. The action of a narcotic drug differs from that of an anesthetic in that pain is relieved before the occurrence of sleep or unconsciousness. Indeed, by administering a properly selected dose, analgesia may be obtained without stupefaction or sleep.

Hypnosis. In the pharmacological sense, hypnosis is a condition of sleep produced by somnifacient drugs. *Sedation* is a milder degree of hypnosis in which the patient is awake but calmed.

Analgesia. This term refers to the obtundation of pain. An analgesic differs from a narcotic in that it characteristically relieves pain without producing stupefaction or unconsciousness.

CHAPTER 2

HISTORY AND THEORIES OF GENERAL ANESTHESIA

HISTORY OF SURGICAL ANESTHESIA

The earliest use of anesthetic agents is lost in antiquity. The Egyptians, who widely practiced surgery, probably had narcotics of various sorts. The Chinese employed hashish (cannabis indica) for its analgesic properties. Pliny, Dioscorides and Apuleius recommended Mandragora (belladonna alkaloids) for use before operations. In addition to drugs, many bizarre and cruel physical methods were devised to render patients temporarily unconscious. For example, the Assyrians asphyxiated children by strangulation before circumcision, a practice used in Italy as late as the 17th century. Cerebral concussion, produced by striking a wooden bowl placed on the head, was also employed.

For many centuries morphine, hyoscine and alcoholic beverages were the main drugs used to ease the pain of surgery. The use of anesthetics for complete and safe abolition of pain in surgical operations is an accomplishment especially of an epoch-making five year period between 1842 and 1847. Before the time of anesthesia, operations were horrible ordeals and the surgeon attempted to shorten the agony by working with great haste. Amputations, for example, were completed in a few seconds and surgeons boasted of their speed. Obviously, careful surgery and delicate treatment of tissues were impossible.

The first gas anesthetic to be discovered was nitrous oxide, by Priestley in 1776. In 1799, Sir Humphry Davy announced that this gas had the ability to destroy pain and suggested its use during surgical operations. For forty-three years this suggestion lay unheeded.

The discovery of surgical anesthesia was an American contribution. Crawford W. Long of Athens, Georgia, had a patient inhale ether while he removed a small tumor from the neck. The subject felt no pain. This was in March, 1842, over three centuries after the chemical discovery of the compound by Valerius Cordus in 1540. Pearson in 1795 had recorded the use of ether inhalations to control the pain of colic, and Beddoes in the next year published a case report of deep sleep induced by ether. American physicians were familiar with the effects of ether due chiefly to Faraday, who had written about the stupefying effects of the compound as early as 1818, as follows, "When the vapor of ether mixed with common air is inhaled, it produces effects similar to those occasioned by nitrous oxide." Nevertheless, in conservative medical circles, ether was considered to be dangerous in amounts which caused loss of consciousness. Medical students in Athens, Georgia, had experimented with Faraday's observation by holding ether parties, or "jags" as they were called. On one occasion they unexpectedly anesthetized a young boy very deeply. Dr. Long often was a leader in these ether frolics, having first witnessed them in Philadelphia several years before, and he became greatly interested in the possibilities of ether as an anesthetic. Finally, he used it for anesthesia on several occasions in his surgical practice. Unfortunately, Long failed adequately to publish his experiences, and his findings remained unknown until ether anesthesia was rediscovered and properly developed by Morton and others, and used as an accepted procedure in surgery.

At this point the history of anesthesia once again reverts to nitrous oxide. In the early 1840's, a peripatetic chemist-lecturer by the name of Colton traveled through New England giving public demonstrations of nitrous oxide or "laughing gas" inhalation for an admission charge of 25 cents. On December 10, 1844, he arrived in Hartford, Connecticut. The newspaper advertisement promised that he would allow volunteers to inhale the gas, and that eight strong men would occupy the front seats to protect those under the influence of the gas from injuring themselves or others. Horace Wells, a dentist in

Hartford, attended the lecture. A person named Cooley volunteered to inhale the gas, and during the inhalation became dazed and belligerent. He jumped from the stage to fight with one of the "strong men" in the front row, but the latter fled. After him went Cooley, who during the chase jumped over a chair, tripped and fell to the ground. The fall brought him to his senses and he returned to his seat sobered and apologetic. Suddenly he noticed that his leg was gashed and bleeding where he had struck the chair during the chase. He was astonished by the presence of the wound for he had experienced no pain. Wells carefully questioned him regarding this, but he insisted that there had been no pain with the injury. The very next day, Wells had one of his teeth extracted painlessly under nitrous oxide, Colton administering the gas. He then used nitrous oxide in his dental practice in Hartford and gave the matter unrestricted publicity.

In January, 1845, Wells went to the Massachusetts General Hospital in Boston to exhibit his gas. The demonstration unfortunately failed, the patient awaking too soon and screaming in pain. Wells met with unjust ridicule because it was not then appreciated that the gas is hard to administer. The wonder is that without special apparatus Wells was successful at all. He was unaware of the deeper degree of anesthesia obtainable with nitrous oxide.

The introduction of ether in the following year placed Wells and nitrous oxide in the background. Greatly embittered, Wells became insane and finally committed suicide. Wells must be given credit for appreciating the importance of nitrous oxide anesthesia and attempting to apply it in dental surgery. In the early 1860's, Colton, the traveling lecturer who 20 years before had by his demonstration initiated the work of Wells, revived the use of nitrous oxide and in a few years the gas was extensively employed in dentistry.

The story meanwhile returns to ether. William T. G. Morton of Boston was a former dental associate of Wells and much interested in nitrous oxide anesthesia. He was also acquainted with the stupefying effects of ether. Morton entered the Harvard Medical School as a student and continued his practice of dentistry in order to defray his expenses. He consulted Prof. Charles T. Jackson, his chemistry teacher, concerning the problem of anesthesia. It is said that Jackson had previously accidentally anesthetized himself and a pharmacist named Burnell into a deep stupor while they were playing cards near a tea kettle, the lamp of which was filled with ether instead of alcohol. Another version is that Jackson accidentally anesthetized himself with ether while inhaling the vapor as an antidote for chlorine gas, of which he breathed too much during a chemistry demonstration before his students. Morton apparently learned from Jackson that ether, to be useful, should be pure sulfuric ether, the kind that Burnell sold. Morton then practiced on himself, the family dog, cats, hens and rats, and finally successfully extracted a tooth under ether September 30, 1846. Soon he asked Dr. J. C. Warren, Professor of Surgery at Harvard Medical School, for permission to make a test trial of ether in a surgical operation. The request was allowed and the day set for the demonstration was October 16, 1846.

The story of this classic demonstration has been retold countless times. The operating room at the Massachusetts General Hospital remains as a memorial to the first public demonstration of surgical anesthesia. In the gallery of this room skeptical spectators gathered, for the news had spread that a second year medical student had developed a method for abolishing surgical pain. The patient was brought in and Doctor Warren, the surgeon, waited in formal morning clothes for gowns, masks, gloves, surgical asepsis and the bacterial origin of infection were entirely unknown in that day. Everyone was ready and waiting, even the strong men to hold down the struggling patient, but Morton did not appear. Fifteen minutes passed, and the surgeon, becoming impatient, took his scalpel and turning to the gallery said, "As Doctor Morton has not arrived, I presume he is otherwise engaged." While the audience smiled and the patient cringed, the surgeon turned to make his incision. Just then Morton entered, his tardiness being due to the necessity for completing an apparatus with which to administer the ether. It is told that Doctor Warren stepped back, and pointing to the man strapped to the operating table said, "Well, sir, your patient is ready." Surrounded by a silent and unsympathetic audience, Morton went quietly to work. After a few minutes of ether inhalation, the patient was unconscious whereupon Morton looked up and said, "Doctor Warren, *your* patient is ready." To this day, anesthetists often inform the surgeon when to start operating by saying, "Doctor, your patient is ready." The operation was begun. The patient gave no sign of pain, yet he was alive and breathing. The strong men were not needed. When the operation was completed, Doctor Warren turned to the astonished audience and said, "Gentlemen, this is no humbug." Dr. Henry J. Bigelow, an eminent surgeon attending the demonstration, remarked, "I have seen something today that will go around the world."

The complete success of this demonstration resulted, after a short initial period of disbelief, doubt and delay, in the rapid introduction of general anesthesia for surgical operations. Dr. Warren wrote, "A new era has opened on the operating surgeon. Who could have imagined that drawing a knife over the delicate skin of the face might produce a sensation of unmixed delight? That the contorting of an ankylosed joint should coexist with a celestial vision? If Ambroise Paré, and Louis, and Desault, and Chesselden and Hunter, and Cooper, could see what our eyes daily witness, how would they long to come among us and perform their exploits once more. And with what fresh vigor does the living surgeon, who is ready to resign the scalpel, grasp it, and wish again to go through his career under the new auspices." Dr. Oliver Wendell Holmes, in addressing his medical class in the fall of 1847, said, "The knife is searching for disease—the pulleys are dragging back dislocated limbs—Nature herself is working out the primal curse which doomed the tenderest of her creatures to the sharpest of her trials, but the fierce extremity of suffering has been steeped in the waters of forgetfulness, and the deepest furrow in the knotted brow of agony has been smoothed forever."

The sequel to the story is an unhappy one. Morton obtained a government patent in 1846. This act and the allegedly unethical methods he used to obtain his patent raised a storm of protest, into which Jackson, Long, and Wells entered as parties in the contest for priority. Wells became insane and committed suicide; Jackson became insane; and Morton, embittered, impoverished and unhappy, died of apoplexy. A monument erected by the citizens of Boston over the grave of Dr. Morton in Mt. Auburn Cemetery near Boston bears the following inscription written by Dr. Jacob Bigelow:

WILLIAM T. G. MORTON

Inventor and Revealer of Anaesthetic Inhalation.
Before Whom, in All Time, Surgery Was Agony.
By Whom Pain in Surgery Was Averted and Annulled.
Since Whom Science Has Control of Pain.

The search for other anesthetics was soon under way. Chloroform had been discovered in 1831, and 16 years later it was tried on animals by Flourens. In the same year (1847), a surgeon in Edinburgh by the name of Simpson successfully tried chloroform anesthesia in man. The suggestion to do so was made to Simpson by McWaldie. The story goes that during the first demonstration the attendant dropped and broke the bottle containing the chloroform. Inasmuch as there was no more immediately available, the operation was undertaken without anesthesia and the patient died almost with the first stroke of the knife. If this death had occurred while the chloroform was being used, it might have postponed the introduction of anesthesia in England for many years.

Strong opposition sprang up against the use of anesthesia in surgery and particularly its employment during childbirth. This opposition came especially from church circles. Simpson effectively met the not unexpected attack by pointing out that God, the first surgeon, had used anesthesia by causing a deep sleep to fall upon Adam while He removed the rib from which Eve was made. Simpson was knighted for his contribution by Queen Victoria, whom chloroform protected from many a labor pain. Chloroform, despite its inferiority to ether, remained the favorite anesthetic in Europe until comparatively recent times.

During the early years of the use of anesthesia, surgeons and nurses did not use the word "anesthesia"; the experience was a new one and there was no expression to describe it. Oliver Wendell Holmes later introduced the words *anesthesia, anesthetic* and *anesthetist.* The following letter was written by Holmes to Morton:

Boston, November 21, 1846.

My dear Sir: Everybody wants to have a hand in a great discovery. All I will do is to give you a hint or two, as to names, or the name, to be applied to the state produced and the agent.

The state should, I think, be called "anaesthesia." This signifies insensibility, more particularly (as used by Linnaeus and Cullen) to objects of touch. (See Good-Nosology," p. 259). The adjective will be "anaesthetic."

Thus we might say the state of anaesthesia, or the anaesthetic state . . . I would have a name pretty soon, and consult some accomplished scholar such as President Everett, or Dr. Bigelow, Sr., before fixing upon the terms, *which will be repeated by the tongues of every civilized race of mankind. . . .*

You could mention these words which I suggest for their consideration; but there may be others more appropriate and agreeable.

Yours respectfully,
O. W. Holmes

It was also Holmes who, when asked to decide whether Morton or another was the discoverer of ether so that the name might be carved on a monument to be dedicated for the purpose, evaded the ticklish question by saying, "Gentlemen, I propose that this monument be dedicated to ether." His true opinion, however, is revealed in the following statement from a letter written years later, on April 2, 1893, to Edward Snell: "Both these gentlemen (Jackson and Wells) deserve 'honorable mention' in connection with the discovery, but I have never a moment hesitated in awarding the essential credit of the great achievement to Dr. Morton." Dr. William H. Welch voiced a similar sentiment when he wrote as follows, ". . . we need not in this instance withhold from Dr. Long the credit of independent and prior experiment and discovery, but we cannot assign to him any influence upon the historical development of our knowledge of surgical anesthesia or any share in the introduction to the world at large of the blessings of this matchless discovery." And again, ". . . in my judgment, after careful study of the evidence, the greater share of the honor belongs to Morton. This was the prevailing opinion of those most competent to judge and best acquainted with the facts of the time. . . ." Perhaps James T. Flexner has aptly summarized the problem by stating that certainly there is enough credit in the discovery of anesthesia for two to share it.

Regardless of the relative merits of the various contestants in the "ether controversy" for priority of discovery, the significance of the "death of pain" resulting from the introduction of surgical anesthesia has been beautifully described by the poet-physician Weir Mitchell, at the semi-centennial anniversary of anesthesia:

Whatever triumphs still shall hold the mind,
Whatever gift shall yet enrich mankind,
Ah! here no hour shall strike through all the years,
No hour as sweet, as when hope, doubt, and fears,
'Mid deepening stillness, watched one eager brain,
With Godlike will, decree the Death of Pain.

THEORIES CONCERNING THE MECHANISM OF ACTION OF ANESTHETICS

The mechanism by which anesthetics depress the activity of the central nervous system is poorly understood. Despite the large amount of investigative work on the subject, the explanations are as yet hypothetical. Many advances have occurred which allow a clearer picture of the mechanism of formation and transmission of the nerve impulse in the peripheral autonomic and somatic nervous systems. Information concerning chemical mediation of stimuli, the rôle of potassium in nervous activity, and the metabolic activity of nerve fibers is not as yet transferable to inhibitory or excitatory processes in the central gray matter. Indeed, the metabolic activity of the brain differs from peripheral nerves in important respects. Even the fundamental mechanisms underlying such a physiological occurrence as normal sleep are obscure. Because of the paucity of conclusive information, the following discussion of the theories of anesthesia will be brief. It should be noted in passing that this lack of knowledge has not interfered seriously with the clinical use of anesthetics or the continuous improvement in anesthetic agents and technics of anesthesia.

There are many agents, physical and chemical, which are capable of producing depression of the central nervous system. Cold, fatigue, oxygen lack, and certain ions (Br, Mg, etc.) are but a few of these. Clinical anesthesia is obtained especially by the use of the hydrocarbons of the methane series. A number of alkaloids also cause marked central depression. It is difficult, therefore, to believe that a single mechanism underlies the action of all these diverse agents. Nevertheless, numerous investigators have sought a unitary explanation by a study of the correlation between physical and chemical properties of drugs and their anesthetic potency. The result of most of this work has been the finding that numerous anesthetic agents show affinities for lipids and for cell surfaces. In some instances, these affinities appear to be quantitatively related to anesthetic strength. Two theories of anesthesia have developed from the knowledge of these affinities, the one usually termed the *"Meyer-Overton law"* and the other known as the *surface tension* *or adsorption theory.* In addition to these two hypotheses, several other explanations of anesthesia exist. For a review of the pertinent literature, the reader is referred to Henderson (1930), Clark (1937), Meyer (1937) and Beecher (1938).

Lipoid Theory. The lipoid theory was advanced by Meyer (1899, 1901). In its simplest terms, it states that there is a direct parallelism between affinity of an anesthetic for lipid and its depressant action. In other words, the more soluble an agent is in oil and the less soluble in water, the more anesthetic it will prove to be. This concept has been formulated as a ratio known as the oil:water partition coefficient and expressed by $\frac{\text{solubility in fat } (S_f)}{\text{solubility in water } (S_w)}$. The higher the coefficient, the more powerful is the anesthetic. Inasmuch as nerve cells and their membranes contain lipids, the anesthetic is thought to gain access to nerve tissue by virtue of its lipid solubility. Changes in cell membrane permeability and in electrical polarization of cells may then occur and in this manner depress reception or discharge of impulses. Evidence for the lipoid theory rests mainly on the fact that the arrangement of a series of chemical agents according to their solubility coefficients agrees fairly well with the order obtained by grouping the same substances according to their anesthetic potency. The many arguments against the theory cannot be given at length but mainly center around the facts that most of the solubilities have been studied *in vitro* with vegetable oils and water rather than with brain lipids and body fluids; that a number of anesthetics fall out of line, notably chloral hydrate; that alkaloids and inorganic ions do not comply with the theory; and that many fat-soluble substances closely related to the anesthetics have no depressant action on the nervous system. In summary, it may be stated that the Meyer-Overton theory points out an interesting analogy which in some way may be concerned with the phenomenon of central nervous system depression.

Surface Tension or Adsorption Theory. This theory was proposed especially by Traube (1904), Lillie (1909) and Warburg (1921, 1930). It relates the potency of anesthetics to their ability to lower surface tension. This property of anesthetics may account for the accumulation of drugs on cell surfaces, but does not explain their depressant action. It is assumed that the physical presence of the chemical in some way alters the surface properties and hence permeability of nerve cells, or interferes with cellular metabolic processes.

Cell Permeability Theory. This theory, advanced particularly by Höber (1907), Lillie (1909, *et seq.*) and Winterstein (1915, 1916), is an extension of the adsorption theory. It holds that adsorbed anesthetics cause a change in the permeability of the cells of the central nervous system. Permeability is decreased by the anesthetic agent whereas stimulation of nerve cells has the opposite effect. The mechanism by which permeability is affected by depressant drugs is thought by Höber and Lillie to be due to the alteration produced in the state of the lipids in the cell membrane. Polarization studies by Spiegel and Spiegel-Adolf (1938) are interesting in this connection and indicate that ether, chloroform, chloral hydrate, phenobarbital, and dial increase the density of the cellular surface films in the cerebral cortex and brain stem.

Colloid Theory. This concept was advanced by Claude Bernard (1875) and elaborated by Bancroft and Richter (1931). The theory holds that an aggregation of cell colloids causes or accompanies anesthesia and that the process is reversible, thereby allowing for recovery. The experimental evidence for the theory is not all that is to be desired.

Inhibition of Oxidation. This theory has not yet been entirely formulated, but evidence being accumulated by cell physiologists and enzyme chemists seems to indicate that certain anesthetics produce central depression or narcosis as a result of interference with the enzymatic components of the respiratory system of nerve cells and the inhibition of the oxidation of glucose by the brain. Most of this work has been performed *in vitro* on cortical tissue slices. For example, Quastel and associates (1932, *et seq.*) have shown that the respiration of slices of rat brain cortex is not inhibited by certain barbiturates or ether in the absence of glucose but is markedly reduced in the presence of glucose by concentrations of the drugs which produce anesthesia in the intact animal. Although the *in vitro* experiments of Jowett (1938) would appear to indicate that ether and alcohol differ from certain other agents in requiring somewhat higher concentrations to inhibit oxidation of glucose than are necessary for clinical anesthesia, nevertheless it is probable that the specific inhibitory effects of anesthetic drugs on glucose metabolism in the brain are related closely to the phenomenon of anesthesia. Many anesthetics, in concentrations employed clinically, greatly inhibit oxidation by brain tissue of glucose, lactate and pyruvate. The inhibition is steady and reversible, related to the concentration of anesthetic, and particularly marked for the pyruvic acid oxidizing system. It is suggested that there is a factor or dehydrogenase in brain highly sensitive to anesthetics which acts as a hydrogen carrier in tissue respiration between pyruvic dehydrogenase and cytochrome oxidase.

Electrical Theory of Anesthesia. Studies of the action potentials of the brain during anesthesia produced by various central nervous system depressants have led some investigators to suggest that anesthesia is due to a decreased negative potential of the cerebral cortex and lessened conductivity through the cerebrospinal axis. The theory, however, is more descriptive than explanatory. To cite but two examples of work in this field, lighter grades of anesthesia (produced by avertin or barbiturates) cause changes in the cortical action potentials similar to those observed during normal sleep. Ether and chloroform produce marked reduction in both the voltage and frequency of the action potentials. CHAPTER 3

STAGES OF ANESTHESIA

The *stages of anesthesia* can best be understood by first appreciating the pattern of action of the general anesthetics. This pattern consists of an *irregularly descending paralysis of the central nervous system.* The term "irregularly" is used in the anatomical sense, and refers to the fact that in the course of descending paralysis the medulla is temporarily spared. Thus, the general anesthetics first depress the cortex, then the basal ganglia and cerebellum, and next the spinal cord. First the sensory and then the motor functions of the cord are affected, probably from below upward. Lastly, the medulla, which apparently is more resistant to anesthetics, is involved, and paralysis of the vital respiratory and vasomotor centers is the usual cause of death from toxic concentrations. It is evident that the most highly developed functions of the nervous system are depressed first, and the phylogenetically oldest functions last. If this anatomical scheme is kept in mind, the signs and symptoms of the several stages of anesthesia will be understood more readily.

Although the divisions are somewhat arbitrary, the stages of anesthesia are four in number as follows:

I. *Stage of Analgesia or Altered Consciousness.* This is the stage corresponding to the action of the anesthetic agent on the higher cortical centers.

II. *Stage of Delirium or Excitement.* This is the stage resulting from the depressant action of the anesthetic on higher motor centers, with a consequent release of automatic lower motor mechanisms. The patient is unconscious in this stage, and hence there are no subjective symptoms. The first two stages comprise what is termed the *induction period.*

III. *Stage of Surgical Anesthesia.* This is the stage during which the action of the anesthetic agent is manifested on the spinal cord. Sensation and spinal reflexes are abolished and muscular relaxation is obtained.

IV. *Stage of Medullary Paralysis.* This is the stage corresponding to the paralytic action of the anesthetic on the vital functions of the medulla and brain stem. It must be carefully guarded against because respiratory failure and vasomotor collapse ensue and rapidly lead to death.

The stages of anesthesia vary somewhat in character and duration, depending upon the type and concentration of the agent used, the speed of induction and the skill of the anesthetist. For example, with ether and chloroform, the traditional stages are usually clearly seen. With ethylene, divinyl ether and cyclopropane, however, induction is more rapid and hence the stages are less clearly defined. When anesthesia is produced by the intravenous injection of barbiturates, unconsciousness occurs within a few seconds so that surgical anesthesia supervenes almost immediately.

The *relative* duration of the stages is constant with all of the volatile anesthetic agents, but the time necessary to reach medullary paralysis varies greatly with different anesthetics. This time is approximately as follows (Guedel, 1937):

Ether	10 to 30 min.	Ethylene	1 to 4 min.
Chloroform	4 to 12 min.	Ethyl chloride	1 to 4 min.
Nitrous oxide	1 to 4 min.	Cyclopropane	½ to 3 min.

The *signs and symptoms* of the four stages of anesthesia may now be described in detail. Significant variations from the usual pattern will be discussed under the pharmacology of the individual anesthetics. The following discussion refers especially to the inhalation anesthetics, and particularly to ether and chloroform.

First Stage: The Stage of Analgesia or Altered Consciousness. The first stage lasts from the first inhalation of the anesthetic until consciousness is lost. It should constantly be remembered by the surgeon, assistants and anesthetist that the patient is still conscious and care should be taken as to what is said and done in his presence. For example, the patient should not be strapped to the table in this stage, nor should the serious nature of his illness be discussed.

Subjective Symptoms. The patient quickly experiences a feeling of warmth which extends over his entire body. A sensation of suffocation, noted particularly with ether, also occurs and is quite unpleasant. It is not due to asphyxia but to the anesthetic agent. Local irritant effects from the vapor or gas may cause smarting of the nose, throat and eyes. As a result of this irritation, lacrimation, salivation and excess secretion of mucus occur unless atropine has been given. Suffocative or irritant sensations may cause the patient to struggle, to breathe irregularly or to hold his breath. This can be prevented by gentle induction and by attempting to get the patient to cooperate. This latter is often done by having the patient inhale in response to the counting or command of the anesthetist.

After the first few deep inhalations, sensations gradually become dulled and abnormal. Soon the body feels stiff, unmanageable, or peculiarly buoyant. Some patients feel as if they were being hurled through space. Thoughts are blurred and uncontrollable, and articulation becomes difficult and indistinct. Hallucinations are not infrequent; the patient often hears loud noises or a buzzing sound, and he may see bright lights. Analgesia gradually ensues with obtundation of the senses of pain and touch. Late in this stage a scalpel incision is perceived as though a blunt instrument were drawn across the skin. Numbness and loss of sensation occur earliest in the skin of the back and extremities. This spreads to the genitalia, then over the rest of the body and finally involves the peripheral sensory distribution of the cranial nerves. Pain is totally abolished just before the onset of unconsciousness.

Sensory functions of both the cerebral cortex and spinal medulla disappear earlier than the motor functions. Experimental evidence shows that sensory cells and synapses are paralyzed before motor units. Surgical procedures cannot be undertaken until the motor components of reflex arcs are sufficiently depressed to allow muscular relaxation.

Objective Signs. During stage I, the skin of the face and neck is flushed. The pupils are normal in size but dilate as the patient begins to pass into the second stage. The pulse is somewhat rapid and the blood pressure may be elevated, mainly from excitement. Study has shown that a rise in blood pressure is often present even before the induction and may amount to from 20 to 100 mm of mercury. Respiration may be increased in rate and irregular, or the breath may be held if the anesthetic is irritating. It is important to have the patient cooperate in keeping the rate and depth of respiration even. The superficial and deep reflexes are intact.

Second Stage: Stage of Delirium or Excitement. This stage extends from the onset of unconsciousness to the beginning of surgical anesthesia. It may be entirely absent, especially in young children. The patient should now be strapped to the operating table, but preparation of the operative field is further delayed because such stimuli may exaggerate the excitement.

Objective Signs. In this stage, the eyes close, the jaws become set and muscular tonus increases. Excitement and marked involuntary motor activity may occur at this time, due to paralysis of the higher motor centers and the consequent release of lower reflex motor mechanisms. The patient may laugh, shout, sing, swear and thrash about. The character of the excitement varies with the speed of induction and the personality of the patient. Delirium is more likely to occur in patients with elevated metabolic rates or in alcoholics.

The *respirations* are likely to be irregular and respiratory reflexes exaggerated. This constitutes one of the greatest dangers of surgical anesthesia, and makes the second stage the one to be most carefully handled. Inasmuch as the patient is unconscious and can no longer cooperate, respiratory reflexes elicited by irritating anesthetic vapors cause spasmodic inspiratory or expiratory arrest, coughing, or alternating periods of shallow and deep breathing. The respiratory irregularities result in an uneven rate of absorption of the anesthetic into the blood stream. After a period of apnea, the patient usually breathes deeply and rapidly and a dangerously high concentration of anesthetic may be quickly reached in the blood. The danger is particularly great with chloroform, a sudden high concentration of which in the coronary circulation may result in ventricular fibrillation and death. The secretion of epinephrine consequent upon painful stimulation from premature operative procedures contributes to the likelihood of such ventricular fibrillation, and therefore operations in this stage of partial anesthesia are particularly dangerous and should be strictly avoided. Most anesthetic deaths occur during the second stage.

It is therefore important that stage II be conducted smoothly. If the induction is stormy, the entire period of surgical anesthesia may be irregular and troublesome. If the character of the respirations permits, the patient should be hurried through the second stage in order quickly to pass the danger period. If the patient holds his breath, the anesthesia should be lightened or the mask removed, so that when respirations are resumed a large amount of anesthetic vapor is not inhaled. Under no circumstances should the anesthesia be crowded if the breath is held. At the end of the second stage, respirations again become regular and deep.

Respiratory Arrest During the Induction Period. There are two types of respiratory arrest occurring in the induction period which are quite different from the reflex apnea arising from concentrated irritant vapors. One is the result of excessive preanesthetic medication, and the other is due to an overdose of the anesthetic (Haggard, 1924; Guedel, 1937). Ordinarily, the threshold for stimulation of the respiratory center is adjusted at the level of the normal CO_2 concentration of the blood. In both types of respiratory arrest, there is a disproportion between the respiratory threshold and the CO_2 level in the tissues.

(1) *Respiratory cessation due to overdose of preanesthetic morphine.* If a patient has received too much opiate, the respiratory minute volume is considerably lowered, and the medullary center is relatively insensitive to the CO_2 level of the blood, despite the fact that the latter may be above normal as a result of the respiratory depression. If hyperpnea develops during induction of anesthesia, as often occurs with the use of the ether open drop method, the CO_2 content of the blood drops much below the threshold of the depressed respiratory center, and respiration ceases when consciousness is lost. Even if breathing does not stop completely, the effective respiratory exchange is insufficient to allow enough ether to be carried from the lungs into the blood, and surgical anesthesia

does not occur. When anesthesia is administered by a closed system, this sequence of events can be avoided because the CO_2 content of the inspired air can be controlled and raised until there is a high enough level in the blood to stimulate respiration. At the termination of anesthesia, during which an elevated concentration of CO_2 has been inhaled, the CO_2 should not be withdrawn suddenly because the abrupt decrease in the blood concentration of the gas may precipitate apnea. Carbon dioxide and oxygen should be given until sufficient anesthetic or opiate has been eliminated to lower the threshold of the respiratory center to the point where the physiological concentration of CO_2 is again effective.

(2) *Respiratory cessation due to overdose of anesthetic agent.* This type of apnea occurs most frequently in apprehensive children who have had insufficient preoperative preparation or medication, and who are given open ether anesthesia by an unskilled anesthetist. Two factors contribute especially to the arrest of breathing. First, the frightened child struggles and cries when the administration of anesthetic is started. Crying causes CO_2 to be blown off and thus diminishes the concentration in the blood of this chemical stimulus to the respiratory center. Second, the ether is usually pushed in an attempt to "rush through the excitement period." Hyperpnea induced by fright causes the concentrated ether vapor to be carried quite rapidly into the lungs, blood and brain. In this way, the central nervous system, because of its large blood supply, is flooded with ether and the threshold of excitability of the respiratory center is elevated. The two factors, a relatively insensitive medulla and a lowered CO_2 content of the blood, combine to stop respiration. The child quickly becomes cyanotic after depletion of the oxygen reserve and the pupils dilate widely. Artificial respiration restores the patient to normal rapidly. The patient is not a poor risk and the operation need not be postponed. Breathing would eventually start spontaneously even without artificial respiration. The circulation, still unimpaired, would soon carry the ether from the flooded brain to other tissues which have lower concentrations of the anesthetic. The CO_2, which accumulates as a result of the apnea, combined with the decreasing depression of the medullary centers, as the ether concentration falls, reinitiate spontaneous breathing. Artificial respiration, however, should always be performed when respiration ceases.

Vomiting and retching may occur, especially if the patient is held in stage II. Premonitory swallowing often heralds the approach of emesis. The patient's head must immediately be lowered and turned to one side, or aspiration of vomitus into the respiratory tract may occur. This unfortunate accident may result either in pneumonia which may prove fatal or in asphyxia from obstruction of the larynx or trachea by food particles. Vomiting rarely attends the use of the rapidly acting anesthetics, apparently because the stage of irritability of the vomiting center is too quickly passed.

Analgesia is present during the second stage but spinal reflexes are still active. Consequently muscular relaxation is insufficient for any but the most superficial operations. Painful procedures are dangerous because the response to such stimulation (including incidental dreams) is exaggerated and may lead to violent physical activity. Bodily injury may result.

The *pupils* which begin to widen at the beginning of the second stage remain dilated until the patient enters the third stage, at which time they contract to a smaller size than normal. The pupillary dilatation of stage II is reflex in nature in contrast to the paralytic dilatation of stage IV. The pupillary reflexes to light are still present in the second stage.

The *skin color* varies with the anesthetic used. It is usually red when ether is used, but may be gray or pale with chloroform. The *pulse* is accelerated, and the blood pressure elevated. All superficial and deep *reflexes* are present.

The proper management of the second stage of anesthesia consists essentially in the restraint of the patient, avoidance of exciting stimuli, and rapid induction. Correct preanesthetic medication is important in insuring against accidents during this stage.

Third Stage: Surgical Anesthesia. Stage III extends from the end of the second stage until paralysis of the medulla and respiratory arrest occur. The onset of surgical anesthesia is not sharply demarcated but the following signs are helpful. (1) The respiratory irregularity of the second stage disappears. (2) The dilated pupils begin to constrict. (3) If the anesthetist suddenly increases the concentration of anesthetic vapor, reflex respiratory arrest and swallowing no longer occur, whereas both of these reflex responses to concentrated vapor can be elicited during the second stage. (4) The eyelid and conjunctival reflexes are now absent. (5) Roving movements of the eyeballs are characteristic of early stage III.

Planes of Anesthesia. The *physical signs* during surgical anesthesia depend on the plane of anesthesia. The third stage is divided into four planes, numbered from i to iv (Guedel, 1937). This division may be simplified by remembering that plane i represents the very onset of stage III, suitable for the simpler operations; planes ii and iii comprise the depths of anesthesia required for most major surgery, while plane iv represents the onset of bulbar paralysis as indicated by respiratory arrest. The major differences in physical signs in the various planes are (1) the character of the respiration, (2) the character of the eyeball movements, and (3) the size of the pupils. Unfortunately, pupillary size is not often helpful because morphine and atropine are usually administered prior to anesthesia.

The usefulness of the above physical signs in judging the depth of anesthesia can be seen from studying Figure 3, and may be illustrated by a few examples. (1) Full and regular respirations, which are both abdominal and thoracic in character, associated with roving eyeballs, inform the anesthetist that the patient is still in plane i. (2) When the regular respirations coincide with fixed eyeballs, the anesthetist knows that the depth of anesthesia has reached plane ii. (3) The beginning of plane iii is indicated by increased abdominal respirations and delayed thoracic inspiratory effort which herald the beginning paralysis of the intercostal muscles. Also at this plane of anesthesia the eyes become fixed in the converged position. The diaphragm compensates for decreased thoracic activity and the increasing downward excursions of the diaphragm during inspiration become more and more noticeable as plane iii advances. The resulting movements of the abdominal viscera may be extremely annoying to the surgeon during an abdominal operation. (4) The transition between the lower half of plane iii and plane iv is marked by complete intercostal paralysis. The patient is never allowed to pass beyond plane iii. (5) Complete cessation of all respiration marks the passage from plane iv of stage III to stage IV.

Respiration. During the major part of surgical anesthesia, respirations are full and regular, somewhat slowed as in physiological sleep, and are often stertorous. This is due to the relaxation of the muscles of the pharyngeal wall with the result that the soft palate vibrates with the respiratory cycle. In planes i and ii, ether, ethyl chloride, divinyl ether and chloroform stimulate respiration, the relative intensity of stimulation being in the order named. The respiratory volume is increased about 25 per cent above normal. In lower plane ii, the agents mentioned begin to depress respiration in the reverse order. Nitrous oxide and ethylene stimulate respiration throughout anesthesia, and do not become depressants by their own action. With these two anesthetics, coincident mild anoxemia stimulates respiration but severe anoxemia depresses it. Cyclopropane neither stimulates nor depresses breathing until plane iii is reached, when respiratory depression begins.

Pupils. The usual changes in pupillary size occurring in the different planes of surgical anesthesia may be seen in Figure 3. When morphine and atropine (or scopolamine) are employed, the action of morphine on the iris usually predominates. Thus the pupil is somewhat constricted in comparison with the usual state for a given plane of anesthesia.

Normally the pupils are constricted as in natural sleep during stage III, especially in plane ii, and react only sluggishly to strong light. Reflex dilatation

FIGURE 3. *Stages of anesthesia.*

Schematic representation of changes in important physical signs at various levels of anesthesia, and the correlation of depths of anesthesia with the control of surgical reflexes and with specific surgical procedures. See text for details.

characteristic of stage II does not occur. The pupillary constriction of stage III is ascribed to abolition of cerebral impulses which inhibit the tone of the oculomotor constrictor center (Edinger-Westphal nucleus).

The pupils dilate progressively as plane iv is approached, and this dilatation is paralytic rather than reflex in character. Pupillary dilatation is greatest with those anesthetics causing the most marked loss of muscle tone, the tone of the sphincter muscle of the iris reflecting, in the deeper planes of anesthesia, the tone of other smooth muscles of the body. Both the direct action of the anesthetic agent and the accompanying anoxia account for the paralytic dilatation. Relatively impotent anesthetics such as ethylene and nitrous oxide, when given with adequate oxygen, do not cause paralysis of the iris. In the stage of medullary paralysis, the pupils dilate widely and rather rapidly. Sometimes sudden dilatation of the pupils is confusing because it may represent either the dangerous advent of plane iv, which requires immediate withdrawal of the anesthetic, or a re-entrance into the second stage, which requires an increase in concentration of anesthetic vapor. The question can be settled quickly by looking for eye movements, testing the corneal and other reflexes, and observing the character of the respiration. Fixed eyeballs and the absence of corneal reflexes always accompany pupillary dilatation arising from dangerously deep anesthesia, and lacrimal secretion has always stopped. When one is in doubt, the anesthesia should be temporarily discontinued.

Eyeball Movements. Activity of the eyeball is an important aid in recognizing quickly the stage and plane of anesthesia. The factors which control ocular activity during anesthesia are unknown. The changes in movements of the eyeball in the various stages are shown in Figure 3, and their significance has been pointed out. The "roving eyeball" is one that rhythmically oscillates, nearly always in a lateral direction, because of alternate contraction of opposite muscles. Often, however, the eyeballs may be eccentric and stationary for several seconds or even minutes, and then move to the corresponding position on the opposite side. If the oscillation is entirely across the palpebral slit, or if the eccentric fixation is extremely to one side, the patient is in the upper border of plane i. These extremes of eyeball movement decrease until they are minimal, at which time the patient is in the lower border of plane i. Plane ii has been reached when all ocular movements cease. The exact type of motor activity of the eyeball is unimportant, although a given individual usually manifests the same type throughout anesthesia. However, the degree of activity serves as a guide to the depth of anesthesia.

Sensory Reflexes. The progressive loss of cutaneous, mucosal and other sensory reflexes as anesthesia deepens may be studied in Figure 3. It is obvious that most abdominal operations cannot be performed easily until plane ii is reached because not until then are the peritoneal reflexes abolished or is muscular relaxation sufficiently complete to render the abdominal wall flaccid. The corneal, genital and peritoneal reflexes are the last to disappear, at which time motor reflex centers in the cord are completely paralyzed.

Peripheral Nervous System. Even during surgical anesthesia, direct excitation of skeletal muscles and peripheral somatic nerves results in the usual responses. While it is true that volatile anesthetic vapors, applied directly to nerves, act as local anesthetics and abolish excitability and conductivity first of sensory and then of motor nerves, this effect requires higher concentrations than can be obtained in living animals by systemic administration.

Blood Pressure and Pulse Rate. These cardiovascular indices are practically normal during planes i and ii. The pulse is usually full. In plane iii both the cardiac rate and blood pressure may be temporarily elevated, but the latter soon falls if anesthesia is sustained in this plane. In plane iv, the blood pressure drops precipitously and the pulse, after an interval of compensatory acceleration, becomes feeble and finally cannot be obtained. Respirations cease before the heart stops beating.

Temperature. Body temperature falls progressively during the course of surgical operations. This is due to lessened muscular activity, increased heat loss from dilated peripheral vessels incident to mild vasomotor depression, the cooling effect of the anesthetic vapors and to interference with the regulation of body temperature by the central nervous system. Thus the patient receiving anesthesia is warmly clothed and blanketed, and operating rooms likewise are kept quite warm. The average fall in rectal temperature during the first hour of ether anesthesia is about two degrees F.

Fourth Stage: Medullary Paralysis. This stage follows plane iv of stage III and ends with death. It starts as soon as the weakened respiration of plane iv entirely ceases, and is characterized by medullary paralysis, respiratory arrest and vasomotor collapse. If there is any indication that the patient is reaching plane iv all other procedures immediately become quite secondary to the necessity for lightening the anesthesia by withdrawing the anesthetic vapor and administering air or oxygen.

The paralytic stage is preceded by several important warning signals. (1) Abdominal respiration signifies the paralysis of intercostal muscles and the presence of plane iii. (2) The pupils start dilating in lower plane ii when the usual preanesthetic medication with morphine and atropine or scopolamine has been employed. The dilatation progresses as plane iii advances, and is almost complete in plane iv. The eyes are dry and lusterless. (3) The pulse quickens in plane iii and continues to accelerate as anesthesia deepens. This is a compensatory response to the respiratory and vasomotor depression. (4) Cyanosis secondary to respiratory and circulatory changes develops as the paralytic stage is approached. It is not a dependable sign, however, when cyclopropane is used.

The *signs of approaching death* in the stage of medullary paralysis from anesthesia are well-known but may be summarized at this juncture. All the superficial and deep reflexes are absent, and the sphincter muscles relax so that the rectum and bladder may empty. The skin is cold and gray, and often the clammy cold sweat of terminal "agony" appears. The pupils are widely dilated and paralyzed, and the eyes fixed and staring. The pulse is either feeble and slow, or more often unobtainable. The blood pressure is at a shock level or unreadable. The abdominal respiration of plane iii becomes shallow and irregular, then labored and gasping, and finally stops.

Respiration ceases before the heart stops beating. This is important because, upon withdrawal of anesthesia and the application of artificial respiration and resuscitative measures, the still active circulation allows excretion of the anesthetic to occur through the lungs, thereby lowering the concentration of anesthetic in the brain. After a few deep artificial respirations, sufficient blood will have passed through the lungs to allow the removal of enough anesthetic to revive the medulla and return the patient to stage III. This obviously would not be possible if cardiac arrest occurred before respiratory failure, under which circumstances artificial respiration would be of no avail.

In this regard, there is a fundamental and important difference between chloroform and other anesthetics. While with most anesthetics respiration ceases first, by the time respiration fails from chloroform, the cardiovascular system is depressed to the point of functional inadequacy. Although the heart still beats, the blood pressure is so low and cardiac systole so feeble that, despite the administration of artificial respiration, circulation through the lungs is insufficient to rid the body of the toxic concentration of the drug.

The *time of death* after cessation of respiration depends on the ratio of metabolic rate to the oxygen reserve. It may be four or five minutes if the metabolic rate is low and the oxygen reserve high, or it may be one or two minutes if the reverse is true. When respiratory arrest occurs during anesthesia, artificial respiration should be started *at once,* regardless of the cause.

Recovery from Anesthesia. The speed of recovery from surgical anesthesia is dependent on the agent used rather than on the duration of anesthesia. The recovery period is relatively long after avertin, ether and chloroform and very short after ethylene, cyclopropane and divinyl ether. After the use of ether and chloroform, the return to full consciousness requires from one-half hour to two hours or longer, and this is then followed by a long postanesthetic sleep. Hyperpnea hastens the emergence from anesthesia produced by volatile agents and this can be induced by carbon dioxide. After ethylene, divinyl ether and cyclopropane, consciousness returns in a few minutes.

Soon after the removal of the anesthetic mask, the respirations become more quiet. The reflexes return in the reverse order of their disappearance. Swallowing movements appear and vomiting may occur, especially if ether was employed. The patient may go through a short period of excitement before awakening. This emergence excitement is usually rather mild as compared with induction delirium, perhaps because aggravating stimuli such as noises, pain, and apprehension are now absent. Furthermore, post-surgical depression limits physical activity. Postanesthetic sleep often follows the return to consciousness and may last many hours. The character of the recovery period following the various anesthetics frequently determines the surgeon's choice of agent. Particularly desirable features are lack of vomiting and early return of cough reflexes. Postanesthetic sleep may or may not be advantageous.

Depth of Anesthesia in Relation to Control of Surgical Reflexes. Knowledge of the order in which the reflexes disappear during the various stages of anesthesia enables one to have the patient in the proper plane for the surgical procedure to be performed, and thus the dangers of too light or too deep anesthesia can be avoided. The time of disappearance of the major surgical reflexes is indicated in Figure 3, but certain additional points deserve mention. Special texts on anesthesia and surgery should be consulted for further details (*see* especially Guedel, 1937; Beecher, 1938).

The *viscera* give rise to little or no pain during operations; thus surgery of the gastrointestinal tract, liver, spleen, pancreas, omentum, kidney, etc., can be performed in the upper half of the first plane of stage III. Traction on the fibrous attachments of these structures, however, causes pain and requires deeper anesthesia. The reflex responses to surgical trauma of the *brain* and *bones* also are annulled in upper plane i anesthesia. The same is true of the skin, but mucocutaneous junctions are very sensitive. Anal or vaginal surgery, therefore, requires deeper anesthesia. In regard to the mucosa of the *posterior pharynx,* more than pain sense is involved because reflex swallowing, stimulated by local manipulation, may be followed by retching and aspiration of débris. This danger is past when lower plane i is reached because the posterior pharyngeal reflex is then inactive. The *laryngeal reflex* is more persistent and necessitates for its abolition anesthesia in upper plane ii. For example, it is impossible to insert an endotracheal catheter under light anesthesia without exciting a prolonged spasm of coughing.

Traction or resection of *nerve trunks* without causing reflex movement or respiratory stimulation (often resulting in vocal cord adduction) can usually be performed in lower plane i. Reflexes arising from *skeletal muscles* are rather complicated. Local reflexes are of no importance but generalized responses depend on the size of the muscle and the type of stimulation. The muscles of the abdominal wall may be rendered sufficiently flaccid for surgery by lower plane ii anesthesia. In contrast, very deep anesthesia is required to abolish the reflexes of the anal sphincter. These are sometimes still active in plane iv. On rare occasion, advantage of this fact is taken by divulsing the anal sphincter in order to stimulate respiration when the latter has ceased.

Traction reflexes are particularly troublesome and require the constant attention of the anesthetist. They arise from pulling on the mesentery or the fibrous attachments of the viscera of the abdomen and pelvis, and manifest themselves in a contraction of the abdominal wall which may push the intestines out through the incision, in respiratory acceleration and in adduction of the vocal cords. A similar spasm of the vocal cords is elicitable experimentally by electrical stimulation of the splanchnic nerves. The respiratory effects may still be present in plane iii, but the response of the abdominal wall is prevented in lower plane ii. When traction on viscera is to be made, the anesthetist must anticipate this maneuver by deepening the anesthesia. A traction reflex still more difficult to combat is the *subdiaphragmatic reflex*. This is present especially in upper abdominal surgery, but in the presence of peritonitis it may be elicited by any intraperitoneal procedure. It manifests itself in an adduction of the vocal cords which causes a characteristic crowing inspiration and grunting expiration. The contraction of the muscles of the abdomen to force expiration against the closed glottis is particularly annoying. Third plane anesthesia sometimes abolishes this reflex but entails troublesome diaphragmatic respiration. An endotracheal airway is the best means of circumventing closure of the glottis, and this holds true for spastic adduction of the vocal cords regardless of the cause.

Smooth muscle tone is affected more by the direct action of the anesthetic agent on the muscle than by reflexes of the nervous system. The musculature of the intestinal tract is greatly depressed in plane iii, and peristalsis stops. At this depth of anesthesia there is also loss of tone of the smooth muscle of blood vessels. These factors, combined with the skeletal muscle flaccidity of plane iii, account for the loss of peripheral circulatory support and the resulting anesthetic shock. It is estimated that anesthesia for one-quarter hour in plane iii causes greater depression of the circulation than anesthesia for two hours in plane i.

Depth of Anesthesia in Relation to Specific Surgical Procedures. Some of the more common surgical procedures and the planes in which they may be performed are indicated in Figure 3. Certain additional points may be emphasized.

During the lower half of stage I, analgesia is present, but no painful procedures are permissible. Consciousness is clouded, and when pain is superimposed on disturbed consciousness delirium may result. The phenomenon is also seen when hypnotics are given to induce sleep in patients who have pain. In order to prevent or control delirium due to pain, morphine should be given or sufficient anesthetic should be administered to carry the depth of anesthesia to plane i of stage III.

Obstetrical analgesia in the first stage of labor is essentially an attempt to make use of stage I anesthesia to relieve pain and yet retain sufficient consciousness to allow the patient to cooperate. The difficulties of obtaining satisfactory obstetrical analgesia are only too well known. Morphine is not permissible in doses capable of alleviating labor pains, and attempts to secure amnesia with scopolamine or barbiturates frequently cause delirium. The use of specific anesthetics in labor will be discussed later.

The first and second planes of stage III anesthesia are suitable for the performance of nearly all surgical operations. Most abdominal surgery is possible in the lower half of plane ii which usually affords maximal muscular relaxation. As a rule, this depth is needed only until the visceral structures are explored, elevated, and the field packed off, and during peritoneal closures. Maximal relaxation of abdominal muscles, however, may not always be obtained before intercostal paralysis has started. This means that the annoyance of increased diaphragmatic movement must be endured if abdominal relaxation is important.

Surgery of the head and neck is usually performed with lower plane i anesthesia in order to prevent vomiting which would prove troublesome. Whenever endotracheal anesthesia is used for any operation, regardless of its nature, upper plane ii anesthesia must be maintained in order to avoid the coughing spasm which the catheter would otherwise induce. First plane anesthesia is essential in all chest surgery in which it is imperative that an active cough reflex be maintained. Tonsillectomy is performed in the lower plane i by those who place emphasis on the retention of the cough reflex. The tongue does not relax until this depth is reached and therefore tonsillectomy cannot be performed with lighter anesthesia. Most surgeons desire upper plane ii anesthesia for tonsillectomy because this allows a well relaxed throat, although the danger of aspiration of blood and débris is enhanced.

In obstetrics, lower plane i affords sufficient anesthesia for normal deliveries and low forceps extractions. The anesthetist must choose between a relaxed perineum and retention of full activity of the uterine musculature. Insufficient perineal relaxation may result in extensive lacerations. Lower plane i anesthesia is safest for most obstetrical surgery.

Third plane anesthesia has few uses in surgery. Its main employment is in obstetrics for internal podalic version and extraction, and for breech delivery.

CHAPTER 4

PREANESTHETIC MEDICATION, TECHNIC OF ANESTHESIA AND ANESTHETIC ACCIDENTS

PREANESTHETIC MEDICATION

Preanesthetic medication refers to the use of one or more drugs prior to the administration of an anesthetic for the purpose of making anesthesia safer and more agreeable for the patient. Such medication is nearly always a routine procedure before general anesthesia.

The more specific objects of this medication are to lessen apprehension and quiet the patient, to reduce the amount of anesthetic needed and in this manner to lessen its toxicity, and to counteract certain untoward or undesirable effects such as the respiratory irregularities of the excitement stage and the excessive flow of mucus or saliva. By decreasing the patient's reflex excitability, proper preanesthetic medication also permits the use of certain inhalation anesthetics (ethylene, nitrous oxide) which otherwise could not possibly produce complete surgical anesthesia without asphyxia. In other words, all preanesthetic medication routines are designed to make the anesthesia more safe and comfortable for the patient and more efficient for the surgeon. It should never be forgotten that the patient comes to the operating room not for an anesthetic but for an operation, and the former serves only to enhance the chances for the success of the latter.

As a rule, most preanesthetic medication consists of a combination of a sedative or narcotic drug with one that will diminish secretions of the respiratory tract and inhibit salivation. The narcotic most commonly used is morphine, but sedatives such as barbiturates are also employed. The agent given to lessen secretions is atropine or scopolamine. The latter drug, in addition, has certain depressant actions on the central nervous system. These medicaments may be discussed individually in regard to their preanesthetic use and value.

Morphine. Since morphine was first used clinically for preanesthetic medication by Labbé and Guyon in 1872, it has occupied the major position in all drug combinations for this purpose. Morphine sulfate in the average adult dose of 10 to 15 mgm is usually injected hypodermically one to one and one-half hours before induction of anesthesia. Some anesthetists prefer to divide the morphine into two equal doses, given respectively two hours and one hour before anesthesia. The time interval between the injection of morphine and the induction of surgical anesthesia should be sufficiently long so that the peak of the respiratory depressant action of the alkaloid has already been passed. It is impossible to depend on a fixed dose of morphine because the character of the response varies with the patient's condition. This is clearly seen in persons with hypothyroidism who are very susceptible to morphine and in whom five mgm may cause profound depression for many hours. In contrast, a patient with hyperthyroidism may receive 15 mgm and note little effect.

Morphine has definite *advantages* as a preanesthetic agent. It relieves pain, decreases anxiety and hence lessens the struggle, excitement and delirium of the induction period. In this way, the onset of anesthesia is made smoother and more rapid. By lessening reflex excitability, morphine decreases the amount of anesthetic needed for surgical anesthesia. This widens the margin of safety and lessens the likelihood of pulmonary and other complications. The respiratory reflexes are sufficiently obtunded so that the respiratory irregularities which are a constant source of trouble and danger in the induction period are mitigated. Morphine narcosis sometimes extends into the postoperative period and aids in relieving pain and promoting rest.

On the other hand, morphine has definite *disadvantages*. The drug is constipating, an action which undoubtedly plays a significant rôle in the high incidence of postoperative ileus. Morphine interferes with the value of pupillary size as a physical sign of the stages of anesthesia. Morphine miosis usually takes slight precedence over atropine mydriasis when the two drugs are used together in the usual doses. The respiratory depression caused by morphine may coincide with that of deep surgical anesthesia. Also, the depression of respiration by morphine, if exaggerated for any reason, may make difficult the induction of inhalation anesthesia because of the lessened respiratory minute volume. This difficulty may be particularly marked with open ether administration, in which instance the concentration of ether must be elevated to induce anesthesia. Spasm of the glottis may then result because the irritability of the larynx is not commensurately reduced by morphine. Rather than increase the concentration of the anesthetic, carbon dioxide should be administered, a simple procedure when a closed system is employed. The mechanism of respiratory arrest during the induction period, due to overzealous medication with morphine, has been discussed on page 37.

Atropine. Atropine is probably second in importance as an agent for preanesthetic medication, despite the increasing use of scopolamine in recent years. Atropine sulfate is usually given hypodermically in the dose of 0.3 to 0.5 mgm. The main purpose of the drug is to prevent excessive secretions of the respiratory tract and salivary glands, but it also acts as a mild respiratory stimulant. Atropine need not be used with anesthetics such as ethylene and nitrous oxide which do not cause mucus or salivary secretion.

Atropine has certain distinct *advantages*. The inhibition of secretions definitely lessens the incidence of postoperative pulmonary complications and vomiting, and allows the use of certain inhalation agents which would otherwise be contraindicated. Atropine in ordinary doses is a mild respiratory stimulant and may aid in offsetting undue depression of respiration by morphine or the anesthetic. It has been claimed that atropine lessens the possibility of cardiac arrhythmias or arrest during the induction of anesthesia, especially when chloroform is used. The usual explanation given is that reflex vagal activity is inhibited. The facts, however, do not support this contention. In the first place, the dose of atropine is insufficient to block the peripheral action of the vagus on the heart; indeed, it may tend slightly to stimulate the vagus center. Secondly, arrhythmias produced by chloroform and certain other vapors are not due to vagal impulses. The nerve impulses which may assist in causing these cardiac effects are mediated through the sympathetic pathways.

The *disadvantage* of atropine is that it interferes with pupillary signs. The anesthetist, however, has more dependable indices of the depth of anesthesia.

Scopolamine. Many anesthetists and surgeons have substituted scopolamine and morphine for atropine and morphine. Scopolamine, like atropine, has a potent inhibitory action on secretions but in addition the alkaloid is also a depressant of the central nervous system and reduces excitement. It is claimed that scopolamine has exceptional tranquilizing properties. Certainly it is effective in relieving the patient's emotional disturbances. The drug also produces amnesia. In the presence of pain, scopolamine is likely to cause delirium and should not be given unless morphine is also used. Scopolamine hydrobromide is injected subcutaneously in the adult dose of 0.3 to 0.6 mgm.

The *advantages* of scopolamine are its tranquilizing action, its ability to inhibit secretions, and its facilitation, when properly balanced with morphine, of the induction of anesthesia. Careful studies on man by Waters and associates (1938) indicate that scopolamine apparently does not increase the medullary depressant effects of morphine but rather antagonizes them. This finding is important because it is usually stated that scopolamine is additive to morphine in this regard.

The *disadvantages* of scopolamine are considered negligible by those who have had wide experience with the drug. It is usually taught that scopolamine differs from atropine in being a respiratory depressant but studies on man do not support this contention. In fact, the alkaloid may exert a stimulating action on respiration. In the experiments of Waters and coworkers to which reference has been made, a total of 128 mgm (!) of morphine was given with 4.2 mgm of scopolamine in six divided doses over a period of two and one-half hours. Sufficient muscular relaxation and anesthesia were obtained with these two drugs alone to enable the repair of a large ventral hernia. This procedure is not advised, but the point of interest is that adequate pulmonary ventilation was maintained. It is evident that scopolamine must have protected against the respiratory depression caused by the exceptionally large amount of morphine. Like atropine, scopolamine interferes with pupillary signs. It should not be used alone for preanesthetic medication in the presence of pain. The main disadvantage of scopolamine is that idiosyncrasy to it is fairly common and the patient may manifest excitement or delirium (page 463).

Barbiturates. The use of barbiturates for and prior to anesthesia is also discussed in Chapter 9. Their employment is ordinarily reserved for producing sound sleep the night before operation. In other instances, the barbiturates are used for basal or obstetrical anesthesia. Occasionally, the ultra short-acting members are used intravenously as general anesthetics for minor surgical procedures. The barbiturates are rarely substituted for morphine because they are not analgesic. Given alone, they do not affect the pupillary responses during anesthesia.

Tribromethanol. Tribromethanol is used primarily for basal anesthesia, so that the patient is unconscious when he reaches the operating room. Avertin is fully discussed in Chapter 7.

Factors Modifying Preanesthetic Medication. The amount of anesthetic necessary to obtain a given degree of anesthesia varies especially with the reflex excitability of the nervous system. The higher the level of the reflex excitability, the greater is the resistance to anesthesia. More anesthetic is then required and the attendant danger is increased. To diminish the reflex excitability and thus increase the margin of safety of the anesthetic agent is one of the main purposes of preanesthetic medication. At certain levels of nervous system excitability, it is impossible, without preliminary medication, to anesthetize a patient with ethylene or nitrous oxide without the occurrence of marked asphyxia. In this connection, a second important factor merits consideration, that is, the oxygen needs of the patient. When the total metabolism is high, due to conditions associated with the patient's disease, more oxygen is required and consequently less room is available in the anesthetic mixture for ethylene or nitrous oxide, and anesthesia may be unsatisfactory or impossible. Under many circumstances, nervous system excitability and oxygen demands tend to rise and fall together. The anesthetist has therefore come to view these two factors as associated with each other in determining the necessity for preanesthetic medication.

The height of reflex excitability of the nervous system is the level from which anesthesia starts. The practical application of this fact is graphically illustrated in Figure 4 (Guedel, 1937). This figure presents the normal basal metabolic rate at different ages as compared with the base line value at birth and extreme old age of 35 large calories per hour per square meter of body surface. The curve depicting basal metabolic rate also serves to show the reflex irritability of the nervous system, and agents used to produce preanesthetic sedation tend to lower both excessively elevated oxygen demands and reflex excitability. In the chart is likewise shown the effect of specific conditions which tend to increase oxygen demand and reflex irritability, and thus elevate further the starting point for the induction of anesthesia. These specific conditions now merit brief consideration.

Specific Factors Modifying Reflex Irritability and Oxygen Demand. The factors which tend to influence reflex excitability and oxygen demand are (1) age, (2) pain, (3) fever, (4) thyroid disease, (5) body build, (6) toxemia, and (7) emotional disturbances. Often several of these factors operate together and mutually influence each other. The influence of *age* on oxygen requirements and reflex excitability may be seen in Figure 4. *Pain* increases the irritability of the nervous system and raises the resistance to anesthesia. Its effects vary in different individuals and are more pronounced, for example, in a hyperthyroid than in a hypothyroid patient. *Elevation of the temperature* of only one degree F. is accompanied by an increase of more than seven per cent in the metabolic rate, and the reflex excitability of the nervous system is correspondingly increased. Emotional disturbances and sensitivity to pain are greater in the presence of fever. *Endocrine dysfunction,* especially of the thyroid gland, notably affects oxygen needs and nervous irritability. Patients with a very muscular *body build* are more difficult to anesthetize than slender asthenic individuals. Certain *toxic states* render the nervous system more excitable. The *emotion* of fear is one of the most important factors in raising reflex excitability. In Figure 4 is presented an example of the influence of several of the factors mentioned in a hypothetical case of hyperthyroidism. The increments over the normal reflex excitability and oxygen requirement due to the disease itself, fear, fever and pain are illustrated, as well as the effect of preanesthetic medication.

The Influence of Preanesthetic Medication on the Depth of Anesthesia. When the weaker anesthetic gases are employed in patients with elevated reflex excitability, an adequate depth of anesthesia may not be obtainable without proper preanesthetic medication. In contrast, when more potent anesthetics such as ether and cyclopropane are employed, any desired depth of anesthesia may be obtained without preanesthetic medication and regardless of the initial level of reflex excitability. However, when reflex excitability is elevated, a proportionately greater blood concentration of anesthetic agent is necessary for a given plane of anesthesia. Under these circumstances, preanesthetic medication decreases the amount of anesthetic required and thus widens the margin of safety.

FIGURE 4. *Schematic representation of the planes of anesthesia obtainable when using various anesthetic agents with and without preanesthetic medication.*

Superimposed on the diagram of the planes of anesthesia is a schematization of the reflex excitability of the nervous system at different ages as depicted by basal oxygen demands (see text). *A, nitrous oxide; B, ethylene; C, ether, divinyl ether* or *cyclopropane.* The vertical lines *A–1, A–2* and *A–3* represent the depths of anesthesia obtainable with nitrous oxide when anesthesia is started at three levels of reflex excitability and oxygen demand. Even under the most favorable circumstances (*A–1*), anesthesia cannot be carried with an 88:12 nitrous oxide-oxygen mixture more than 15 per cent through stage III, *i.e.,* a little below mid-plane i, and therefore nitrous oxide has been given a potency rating of 15 per cent. With ethylene and sufficient oxygen to prevent anoxia, under favorable circumstances (*B–1*) anesthesia can be carried to the upper border of plane ii, *i.e.,* 25 per cent through stage III, and therefore this gas has been given a potency rating of 25 per cent. If anesthesia with nitrous oxide or ethylene begins from higher levels of reflex excitability, these gases are even less effective (*A–2, B–2*). If the starting point is sufficiently high, anesthesia may be impossible (*A–3, B–3*) without the intervention of anoxia or preanesthetic sedation. Regardless of the initial level of reflex excitability, ether, divinyl ether and cyclopropane, unassisted by anoxia or preliminary medication, can carry anesthesia to medullary paralysis (*C–1, C–2, C–3*) and therefore have a potency rating of 100 per cent.

The figures *a, b, c* and *d* indicate increments of added reflex excitability and excess oxygen

Additional Preanesthetic Preparation of the Patient. Only the more important points to be observed in the preanesthetic preparation of the patient can be mentioned here (for details, *see* Symposium, 1940). The diet should be light during the day prior to operation, and it is desirable to increase carbohydrates and proteins and to restrict fats in order to protect the liver (page 66). If the operation is an emergency and the patient has recently ingested food, the gastric tube should be passed and the stomach emptied to lessen the danger of aspiration or asphyxia should vomiting occur. The former routine of purging is obsolete.

Special attention should be given to the cardiac, pulmonary, renal and hepatic functions during the usual physical and laboratory examinations of the patient. The results of these often determine the choice of the anesthetic agent. A poor choice greatly increases the surgical risk and may result in death.

The patient should be kept sufficiently warm during the operation to minimize the loss of body heat occurring during anesthesia. The eyes should be closed and protected from anesthetic vapors. The corneal reflex is not used as a physical sign because of the danger of inflicting damage. The nose and lips may be prepared with vaseline, and the airway is carefully examined to make certain that no potential obstruction such as false teeth or removable bridgework is present.

POSTANESTHETIC MANAGEMENT

Postoperative care is chiefly a surgical question but certain points may be mentioned here concerning the postanesthetic management. (For details, *see* Symposium, 1940.) Skillful nursing is the main requirement. The patient must be watched continuously until conscious. If vomiting occurs, care should be taken to prevent aspiration. With some agents, vomiting during the recovery phase is so frequent that it has come to be looked upon as an attendant phenomenon rather than as an accident. The tongue should be prevented, by a mechanical airway, from falling back into the throat and asphyxiating the patient.

On some surgical services, the periodic inhalation of carbon dioxide (five or 10 per cent) is routinely used to cause hyperpnea and clear the bronchial tree. The purpose of this is to prevent atelectasis and reduce the incidence of postanesthetic pneumonia. The statistical evidence for the value of this procedure is inconclusive. The inhalation of carbon dioxide is also helpful to arrest persistent postoperative hiccoughing.

Attention should be paid to the recovery of bladder and intestinal functions. Postanesthetic urinary retention and intestinal ileus are frequent and troublesome. In addition to numerous mechanical measures for obtaining relief and hastening recovery, certain drugs such as choline esters, posterior pituitary and prostigmine are available.

The postoperative relief of pain is a problem which depends largely on the type of surgical procedure performed. In general, relief with opiates may be allowed for twenty-four hours, but after the first postoperative day analgesic medication should not be given in amounts or at intervals which will interfere with the proper interpretation of the surgical results or mask the onset of complications.

TECHNIC OF ANESTHESIA

The many methods and instruments used in the administration of the various anesthetic agents cannot be fully described here. The problems are technical and are best learned by actual training on an anesthesia service. Certain general features, however, must be pointed out. Ethylene, cyclopropane and nitrous oxide

---

demand in a hypothetical case of hyperthyroidism in a 20 year old youth. The increment due to *hyperthyroidism* is represented by *a; pain, b; fever, c; emotional disturbance, d.* The vertical line *d–e* represents the effect of intelligent preanesthetic sedation on reflex excitability. Thus surgical anesthesia with the weaker anesthetic gases is made possible and higher concentrations of oxygen may be used. If the more potent agents are used, a given level of anesthesia can be obtained with a lower concentration of anesthetic. (After Guedel, 1937.)

require special gas machines for their use. They cannot be given except through a closed system with oxygen or air. Ether, divinyl ether, ethyl chloride and chloroform can be given either by the *open, semi-open,* or *closed* technics. Tribromethanol, on the other hand, is given rectally.

Open Method. Ether may be used to illustrate the open method of administering an anesthetic because the open drop ether technic is still the most common type of anesthesia used in the United States. The open method consists in dropping the anesthetic on a multi-layered gauze mask with free access of air, and no attempt is made to confine the vapor.

The rate at which the ether is dropped varies with the size of the drop and the thickness of the mask; it is usually 12 drops during the first minute, 24 during the second, 48 during the third and 96 during the fourth. By this time the ordinary mask is saturated and the concentration of ether under the mask has approached 10 volumes per cent. Also, by this time, the patient is in the second or excitement stage of anesthesia. The rate of approximately 100 drops per minute is continued for about 15 minutes. During this interval, the concentration of ether under the mask is much higher than is later needed to maintain the desired depth of anesthesia. The reason for this procedure is that the brain attains a given saturation with ether in a shorter period than do the other tissues which then act as a huge buffer system withdrawing anesthetic from the brain until all the tissues obtain their quota. In the ordinary anesthetization of an adult one must therefore keep the mask completely saturated for approximately 10 to 15 minutes. The rate of administration of ether is then slowly decreased so that the average rate during the second 15 minutes of anesthesia is approximately 50 drops per minute. During this time equilibrium is being reached, a process probably requiring between 30 and 45 minutes. The rate during the third 15 minutes is approximately 20 to 30 drops per minute. For the fourth 15 minute interval and the subsequent period of anesthesia, the rate of administration is kept at a maintenance level of approximately 12 to 24 drops per minute. The concentration of ether in the mask during this maintenance period is between three and five volumes per cent. The foregoing description is not quantitative and serves only as a guide. The open drop method is wasteful and only a small fraction of the ether used actually enters the body. During an hour's anesthesia, three-quarters to one pound of ether may be used in contrast to the two ounces needed when the closed carbon dioxide absorption technic is employed.

Chloroform anesthesia by the open method requires the same technic described for ether. Chloroform, however, is much more potent and less volatile than ether. For every six drops of ether placed on the mask, one drop of chloroform may be considered as the approximate equivalent.

Semi-open Method. This technic is also called the semi-closed method. A gauze mask is used as in the open method but a towel is so placed on the face and around the base of the mask that the escape of anesthetic vapors is greatly decreased and more carbon dioxide is retained. The rebreathing of this carbon dioxide prevents the apnea which may occur during induction by the open method (page 37), and facilitates the rapid onset of anesthesia.

The anesthetist has several means for controlling the administration of anesthetic vapor by the open or semi-open mask method. Not only can he regulate the rate at which ether is dropped on the mask, but the distance at which the mask is held from the face and the amount of air accessible to the patient can be changed. Fine control is especially important during the induction phase.

Closed Method. With this method, the patient rebreathes the anesthetic mixture. The usual apparatus consists of a tight fitting mask, rebreathing bag, and provisions for the absorption of moisture and carbon dioxide and for the introduction of anesthetics, oxygen and carbon dioxide. In the strict sense, this is the only type of system which can be considered "closed." Anesthesia by the closed method has many advantages, chief among which are the adequate control of respiration which it allows, economy in the cost of anesthesia, preservation of body heat and water, smoother induction, and moment to moment control of depth of anesthesia.

When nitrous oxide, ethylene, or cyclopropane is used with oxygen and the closed method, there is liberation of nitrogen from the body fluids through the lungs. This nitrogen represents that which was held in simple solution in the blood as a result of its presence to the extent of 80 per cent in the inhaled air. The anesthetic mixture contains no nitrogen and consequently the partial pressure of nitrogen in the alveoli of the lungs is greatly reduced, causing an escape of nitrogen from the body fluids and its accumulation in the breathing bag (Guedel, 1937). Three liters of this gas may be liberated through the lungs during the first hour of anesthesia, and in a closed system will greatly dilute the anesthetic mixture. Unless the breathing bag is emptied periodically to dispose of the accumulating nitrogen, the anesthetic mixture will become too weak to maintain surgical anesthesia, or the dilution will be made at the expense of the available oxygen which is already minimal for body needs when ethylene or nitrous oxide is employed.

It should be emphasized that the development of instruments and machines to facilitate the administration of anesthesia does not lessen the necessity for close observation of the patient. Nothing can replace the alert and intelligent attentiveness of a trained anesthetist. No rigid routine can be adopted with safety, and the vital signs must be continuously watched from moment to moment so that any untoward change may be properly and immediately countered. A gas machine can assist but not replace an anesthetist.

ANESTHETIC ACCIDENTS

A number of accidents may occur incident to the administration of an anesthetic. It is important to anticipate and prevent these, for they may prove fatal. Only those related to the pharmacological actions of anesthetics will be discussed in detail. The classification used here is that of Guedel (1937).

Circulatory Accidents. *Anesthetic Hypertension.* Asphyxia and the release of epinephrine are the two major causes of a sudden rise in blood pressure during the course of anesthesia. The asphyxial rise is more intense when accompanied by struggling and is especially likely to occur during the induction period. The discharge of epinephrine also is apt to occur during induction, due to fear or struggle, and the blood pressure may increase sharply. As anesthesia deepens, hypertension due to epinephrine becomes less and less pronounced. The dangers incident to hypertensive crises lie in the possibility of vascular hemorrhage in persons with diseased vessels, or acute dilatation of the heart in the presence of preexisting myocardial damage. Control of these accidents depends on careful selection of patients, proper management of induction, and prevention of oxygen want and carbon dioxide accumulation.

Anesthetic Hypotension. The principal causes of dangerous hypotension during anesthesia are *hemorrhage* and *shock.* Regardless of the etiological mechanism, the ultimate result is tissue anoxia. Hemorrhage is mainly a surgical problem. Until transfusion can be performed, intravenous administration of fluids and the inhalation of a high percentage of oxygen are helpful. Carbon dioxide may also be given because it increases the tone of arterial walls. Indeed, the hypotension produced experimentally in anesthetized dogs hyperventilated mechanically results from the combined effects of the anesthetic and the loss of CO_2 (Seevers and coworkers, 1940).

Shock, whether due to the anesthetic or to the surgical procedure, has the same underlying pathological physiology. The mechanism of shock and the usual measures employed in treating it are described elsewhere (page 586). It can be prevented by avoiding anesthesia deeper than is absolutely necessary, by conserving body heat and moisture, by maintaining an optimal CO_2 level, by allowing sufficient oxygen at all times, and by treating the tissues as gently as possible.

Ventricular Fibrillation. This arrhythmia is more fully discussed under chloroform anesthesia. Although chloroform is the chief offender and ethyl chloride is next in order, every anesthetic is potentially dangerous in this regard. Ventricular fibrillation is most likely to occur in the induction phase, and results not only from the direct action of the anesthetic agent on the heart but also from the discharge of epinephrine and overactivity of the sympathetic nervous system. Delirium or operative stimuli in the second stage are added precipitating factors. The respirations cease almost immediately after the pulse, and this respiratory arrest should not be mistaken for a temporary apnea or the cardiac state will remain unrecognized for some time. Although treatment is usually futile, immediate artificial respiration and intratracheal oxygen are indicated. Cardiac massage through the diaphragm may be performed. The danger of ventricular fibrillation is reduced by proper preanesthetic medication, by smooth and rapid induction, and by avoidance of premature surgical procedures and the use of epinephrine for any purpose during early anesthesia.

Respiratory Accidents. *Respiratory arrest* during anesthesia may occur for a variety of reasons. The seriousness of the apnea depends upon the causative factors and the stage in which it occurs. Apnea of central origin observed in the induction phase or late in anesthesia has been discussed under the stages of anesthesia. Central respiratory arrest is occasionally due to increased intracranial pressure. In patients who have elevated cerebrospinal fluid pressures or brain tumors, one should be cautious in the use of opiates or anesthetics which further increase intrathecal pressure.

Respiratory arrest also occurs from *breath holding* which is seen only in stage I and is due to emotional disturbance or laryngeal irritation. *Pharyngeal spasm* is more troublesome, appears at the end of stage I, and may persist intermittently through stage II. Attempts to maintain an airway or force oxygen past the obstruction usually fail, and one must wait until the CO_2 concentration rises and the oxygen content of the blood falls sufficiently to break through the spasm and stimulate breathing. *Laryngeal spasm* is the result of reflex adduction of the vocal cords due to their direct irritation or to painful stimuli elsewhere. Laryngeal spasm from direct stimulation disappears in plane ii. Spasm of the vocal cords secondary to painful stimuli has been discussed.

If the muscles of the lower jaw are sufficiently relaxed, the base of the tongue may obstruct respiration by falling against the posterior wall of the pharynx. This has been misnamed *tongue swallowing.* It is observed rarely during the first two stages of anesthesia but may occur after the patient is returned to his bed if he is placed in the supine position. The danger may be circumvented by the use of a pharyngeal airway or by holding the lower jaw forward. Another form of mechanical respiratory obstruction is due to *aspiration of débris.* Foreign objects may lodge in the pharynx, trachea, bronchi or, if liquid, in the lungs. Teeth, sponges, instruments, and blood, pus or mucus are the common offenders. Secretion of mucus should be controlled by adequate doses of atropine or scopolamine. Postural drainage and suction may be employed to prevent aspiration of blood or pus. Endotracheal anesthesia with suction is the best method of avoiding aspiration during lung surgery for abscess or bronchiectasis. The aspiration of *vomitus* is usually avoidable. Reflex vomiting is more likely to occur during lower stage II anesthesia than at any other time. The stomach should be empty before inducing anesthesia, and if one is in doubt it is imperative that a gastric tube be passed; but even this cannot be depended upon to remove large particles. Aspiration usually occurs when emesis follows a long period of retching and breath holding. In spite of an alert anesthetist, the vomitus filling the pharynx may be drawn down into the trachea. Postanesthetic vomiting is less dangerous but must be properly treated. Carbon dioxide may be inhaled to hasten emergence from anesthesia and thus lessen the likelihood of vomiting. The pulmonary complications from aspirated vomitus are often severe and may be fatal.

Miscellaneous Accidents. *Massive collapse of the lung* secondary to anesthesia is usually caused by shallow respiration and bronchial obstruction, particularly from mucus. Atelectasis is due to complete absorption of gases by the blood flowing through the lung distal to an occlusion of a main bronchus, and occurs within a few minutes. It may not be noticed if a closed system with high oxygen tension is being used. As soon as the anesthetic is stopped, however, cyanosis and dyspnea are apparent and physical examination reveals evidence of pulmonary collapse. Atelectasis often results in serious postoperative pneumonia. Prevention depends upon maintaining sufficient depth of respiration by inhalation of CO_2 if necessary, and vigorous hyperpnea induced with CO_2 at the end of each operation in which breathing has been shallow. In treating fully developed atelectasis, oxygen and carbon dioxide should be administered for an hour or longer, and direct bronchoscopic removal of the mucus plug may be attempted if early evidence of improvement is not forthcoming.

Convulsions may occur occasionally under anesthesia. (*See* reviews by Rosenow and Tovell, 1936, and Lundy, 1937.) Oddly, most of them have taken place under ether, and the term "ether convulsions" has arisen to describe this phenomenon. A dramatic description of the convulsion is given by Hudson (1936). The convulsion is epileptiform in character and usually develops in children with infectious or toxic processes and high fever. Of 144 cases reviewed by Lundy (1937), 53 per cent of the patients were children. The convulsion may supervene in any stage. Anoxemia is not the cause, for the attack may occur in the presence of a high oxygen tension in the blood. Nor is ether alone the cause. Experiments on animals have indicated that clinical convulsions possibly may result from a combination of anesthesia, fever and factors causing metabolic acidosis and elevated carbon dioxide tension in the blood (Cassels, Becker and Seevers, 1940). The intravenous injection of short-acting barbiturates has been reported to control ether convulsions.

Postanesthetic fever is rare and proof that the anesthetic is to blame is lacking. A high temperature reaching 108 to 110 F. may develop several hours after operation; usually no cause is found for it, and the patient dies despite therapy.

Cerebral asphyxia may result in irreversible cortical damage if prolonged beyond the limit of tolerance of the nerve cells for anoxia. The small pyramidal cells of the cortex can withstand oxygen lack for only six to eight minutes. Cortical injury is permanent and results in many neurological and psychiatric syndromes, including parkinsonism, athetoid movements, mental defects, idiocy and decorticate rigidity. Nitrous oxide is the worst offender because it often necessitates limitation of oxygen. (*See* Courville, 1936, 1938, and 1939, for review; also Gildea and Cobb, 1930, for effects of experimental anoxia on the cortex.)

Anesthetic Explosions. Explosions are among the most serious accidents that can occur in anesthesia. Oxygen, carbon dioxide, nitrous oxide and chloroform are noninflammable. Oxygen is important in explosions, however, because it supports combustion. Oil should not be used on the valves or gauges of oxygen tanks because the oil may ignite when suddenly exposed to high oxygen pressure and cause a violent explosion. Oxygen also must not be mixed in the same cylinder with ethylene. It is a myth that carbon dioxide reduces the inflammability of anesthetic agents as used clinically. Although chloroform is not inflammable, it is oxidized in the presence of an open flame to phosgene gas (carbonyl chloride, $COCl_2$), chlorine and hydrochloric acid, all of which cause pulmonary irritation, cough and dyspnea. Collapse may even ensue and phosgene in concentrations as low as 1:40,000 is said to be capable of causing death from pulmonary edema.

The inflammable and explosive agents used in anesthesia are ether, ethylene, cyclopropane, divinyl oxide and ethyl chloride. Fortunately, the incidence of anesthetic explosions is low and only two deaths from this cause occurred in over two million anesthesias (Woodbridge, 1939). The precautions concerning the use of open flames and the cautery are mentioned under the particular anesthetic agents. Electric sparks are the cause of most accidents, and are mainly static in origin. Static sparks originate from friction in opening and closing valves, in the rubber breathing bag, in the flowing of dry gases through the anesthetic apparatus, etc., and are always a potential source of danger. Static electrical discharges can be prevented, to some degree, by elevating the humidity of the air in the operating room to 65 per cent or more. Complete and suitable grounding of the anesthetic apparatus, patient and surgical team is also effective but often difficult or impractical, necessitating conductive floors and shoes, and drag chains from tables and anesthesia machines. A technic of high resistance intercoupling (Horton intercoupler) which provides safety from anesthetic explosions due to static sparks has also been devised (Woodbridge, Horton and Connell, 1939). Cotton material (not wool or silk) for clothing and drapes should be used, and towels and drapes may be rinsed, after laundering, in 0.5 per cent calcium chloride solution in order to decrease the static potential which can be induced on them by friction. The wetting of the anesthetic breathing bag and hose before use is also an important safeguard against static ignition in the apparatus. An explosive anesthetic mixture should not be flowing through the apparatus at the time the mask is applied to the patient's face, and the anesthetist should not remove the mask more frequently than is absolutely necessary.

Anesthetic Deaths. It is desired only to emphasize that the anesthetic is not always the cause of death. Indeed, the cause may be extremely difficult to determine. There are several quite famous historical examples to illustrate that death may be due to causes other than anesthesia. The experience of Sir James Simpson about to perform his first operation under chloroform has already been mentioned. Death has even occurred in a patient who was breathing air through a gauze mask in the belief that he was receiving chloroform. The tendency to attribute death under anesthesia to ill-defined causes such as "anesthetic shock" and "status thymolymphaticus" is rapidly disappearing. Improvement in anesthetic technic and careful selection of patients have resulted in a marked decrease in mortality. Also, more frequent and careful autopsies have aided in discovering the real causes of death during anesthesia.

PROPERTIES OF THE IDEAL ANESTHETIC

The qualities desired in an ideal anesthetic have been well summarized by Seevers and Waters (1938) who point out that the desires of four individuals must be satisfied as follows: The *patient* desires not only rapid and pleasant induction with an anesthetic which is non-irritating and free from unpleasant odor, but also a recovery period which is free of discomfort. The *surgeon* would be satisfied if the agent were not explosive, if it were capable of producing complete muscular relaxation and did not increase capillary bleeding. The *anesthetist* desires an anesthetic to have a wide margin of safety, to be excreted from the body entirely unaltered, to cause a minimum of functional or organic injury during and following its use, to be sufficiently potent so that a high percentage of oxygen may be employed in the anesthetic inhalant mixture at all times, and to diffuse sufficiently rapidly to allow moment to moment control of the depth of anesthesia. The *manufacturer* is interested in having an anesthetic which can be produced simply and inexpensively, purified without difficulty and stored without undergoing chemical changes.

No known anesthetic fulfills all the qualifications listed. Seevers and Waters are inclined to believe that the ideal anesthetic should be a gas. At least, agents such as barbiturates and tribromethanol which depend for their rapidity and lability of action on renal elimination or destruction in the body are not sufficiently safe to be widely serviceable as general anesthetics. Were it a more potent gas, nitrous oxide would qualify as the ideal anesthetic.

CHAPTER 5

GENERAL ANESTHETICS

I. ETHER AND CHLOROFORM, DIVINYL ETHER, ETHYL CHLORIDE AND TRICHLOROETHYLENE

The general anesthetics to be discussed in the following pages are the volatile liquids—*ether, chloroform, divinyl ether, ethyl chloride* and *trichloroethylene;* the gases—*nitrous oxide, ethylene, cyclopropane* and *acetylene;* and the basal anesthetic, *tribromethanol.*

Advantages and Uses of General Anesthesia. General anesthesia is essential when complete unconsciousness and adequate relaxation of muscles are desired, and when movement of the patient may imperil the success of the operation. It has the advantage over spinal or local anesthesia of removing the factors of anxiety and fear. General anesthesia is often necessary in abdominal operations of an exploratory character when the nature of the subsequent surgical procedures cannot be fully anticipated. Furthermore, it is necessary in thoracic surgery where spinal anesthesia is not safe. Finally, it is useful in states of extreme excitability of the central nervous system, as in strychnine convulsions, tetanus, etc. The intravenous use of the soluble barbiturates has largely replaced the inhalation anesthetics for treatment of these convulsive states.

ETHER AND CHLOROFORM

Ether continues to be the most widely used general anesthetic. It is the standard with which all newer anesthetics are compared and therefore its actions will be considered in detail. Chloroform, because of its toxicity, has largely disappeared from use. It is of great historical interest, however, and in some parts of the world, especially in the tropics, is still widely employed. Because of these facts and also for the reasons that chloroform contrasts sharply with ether in many ways and teaches a number of important points about general anesthesia, chloroform and ether will be discussed together.

Chemistry and Preparations. The chemical properties of ether, $C_2H_5OC_2H_5$, and chloroform, $CHCl_3$, are too well known to warrant discussion. It may be stated, however, that numerous studies on the relationship of chemical structure to pharmacological action indicate that the ethyl radicle is apparently potent and relatively safe for the production of central nervous system depression, and that the introduction of ether groups enhances anesthetic potency. These facts are exemplified in ethyl ether which combines both structures. The inclusion of halogens, chlorine or bromine, in the alkyl group of an anesthetic increases the depressant power, but at the same time the toxicity for certain organs, particularly the heart and liver, is increased. Chloroform is a pertinent example. One interested in the extensive and important question of the relation between chemical structure of anesthetics and their clinical actions and usefulness is referred to Shonle (1932) and Killian (1934).

Ether, U.S.P., B.P., contains from 96 to 98 per cent of $(C_2H_5)_2O$, the remainder consisting of alcohol and water. The U.S.P. specifies that ether to be used for anesthesia must be preserved only in small, well-closed containers, and is not to be used for this purpose if the original container has been opened longer than 24 hours. It has been demonstrated, however, that U.S.P. ether supplied in large metal containers stoppered with cork does not deteriorate over a period of many weeks when the containers are opened repeatedly for transfer of the contents to small anesthetic cans, but well stoppered in the interim. Such ether is suitable for anesthesia and the cost is materially reduced (Gold and Gold, 1934; Dooley, 1935; Morrison, 1938; Hediger, Chenoweth and Gold, 1940).

Chloroform, U.S.P., B.P., contains between 99 and 99.5 per cent of $CHCl_3$, the remainder consisting of alcohol. Care should be taken not to vaporize chloroform in the presence of a naked flame, because of the production of noxious gases.

Pharmacological Actions

Central Nervous System. The typical action of the methane anesthetic series and the probable mechanisms of this action have already been discussed. Also, the signs and symptoms of each stage of anesthesia have been described. Certain additional points, however, should be stressed. Chloroform is the most potent of all the inhalation anesthetics, being over three times more depressant than ether per unit of concentration in the blood. Both ether and chloroform are 100 per cent anesthetics inasmuch as they carry the patient through all planes of surgical anesthesia to respiratory arrest from any level of reflex excitability without the intervention of oxygen deprivation or preanesthetic medication (Figure 4). None of the other inhalation anesthetics produces quite the same degree of muscular relaxation during stage III as do ether and chloroform, and some are quite inferior in this respect. To obtain complete abolition of spinal reflexes and muscular relaxation sufficient for abdominal surgery, small amounts of ether are often used to supplement nitrous oxide, ethylene or cyclopropane.

Respiration. *Local Actions.* Chloroform is more irritating than ether to the skin and mucous membranes. As an anesthetic, however, ether is more irritating to the respiratory passages because a concentration of ether three times higher than that of chloroform in needed in the inspired air. Thus ether causes greater stimulation of bronchial secretions and is often contraindicated in patients with pulmonary disease. Both chloroform and ether also markedly stimulate the flow of saliva during induction of and recovery from anesthesia, but salivation is inhibited during the deeper planes of surgical anesthesia.

Systemic Actions. The character of respiration in each stage of ether anesthesia has already been presented, as well as the types of respiratory arrest which may occur. It is well to reemphasize the fact that most acute anesthetic deaths occur in stage II, and are due to irregular breathing which results in sudden changes in the concentration of anesthetic in the body.

Ether and certain other volatile anesthetic agents directly stimulate the medullary respiratory centers, despite the concurrent depression of other levels of the central nervous system. Thus there is an increase in respiratory minute volume during planes i and ii of stage III (Figure 3). Below lower plane ii, both ether and chloroform depress respiration and raise the threshold of excitability of the respiratory center to carbon dioxide and to afferent stimuli. Cheyne-Stokes respiration is sometimes seen when chloroform is used but is rare with ether. In the paralytic stage, breathing stops before the heart beat ceases with both chloroform and ether. Functionally, however, the cardiovascular system becomes inefficient during chloroform anesthesia before respiration actually ceases.

Heart and Circulation. *Ether.* The cardiac rate is increased during the phase of induction when ether is used. This is due mainly to the release of epinephrine. The blood pressure, after a preliminary rise during the induction period, remains quite normal during surgical anesthesia with ether, even if anesthesia continues for some time. In plane iii, however, 15 minutes of ether anesthesia may cause as great a fall in blood pressure as two hours in the second plane. This is due to the depression of smooth and skeletal muscle tone and a consequent loss of support to the circulation. Inasmuch as the great majority of surgical operations do not require third plane anesthesia, ether is relatively innocuous to the circulation when it is expertly administered.

Ether causes some peripheral vasodilatation, mainly by a direct action but in part through mild central vasomotor depression. The blood flow through peripheral arteries is definitely enhanced during light ether anesthesia (Mann and coworkers, 1935). The skin, especially that of the face, is red, and the cerebral and meningeal vessels, whose responses often parallel those of the face, are also dilated. The cerebrospinal fluid pressure, as a result, rises (Myerson and Loman, 1932). In the paralytic stage, the vasomotor center is seriously depressed and the blood pressure falls due to peripheral vasodilatation. The heart remains unimpaired even at the time when respiration stops. The circulation is inefficient, however, because the peripheral vascular depots are flooded. The excellent status of the heart at the stage of respiratory failure allows for the revival of the patient by prompt restoration of pulmonary exchange. This can be accomplished by artificial respiration, or by inserting a small catheter into the trachea and delivering an adequate flow of oxygen directly to the lungs.

Ether can depress the heart directly but only with concentrations higher than those obtainable during anesthesia. For example, the lethal blood concentration of ether is about 160 mgm per cent. The perfused, isolated oxygenated heart, on the other hand, is capable of withstanding an ether concentration of approximately 450 mgm per cent, nearly three times that necessary to cause respiratory failure. In this regard, ether contrasts sharply with chloroform. A concentration of chloroform of 10 mgm per cent, if prolonged, is demonstrably injurious to the heart and 15 mgm per cent may cause cardiac arrest. These harmful concentrations are exceeded in order to obtain clinical anesthesia. The evidence indicates that chloroform is 25 to 30 times more toxic to the heart than is ether.

Despite the absence of clinical evidence of disturbed cardiac function during ether anesthesia, electrocardiographic changes may be noted (Kurtz and coworkers, 1936). The pacemaker may be shifted downward, and extrasystoles may occur. The latter are auricular rather than ventricular in origin, however, and the ominous types of arrhythmia seen with chloroform and toxic concentrations of cyclopropane do not occur. Ether also differs from cyclopropane and chloroform in that it does not sensitize the automatic tissue of the ventricle to epinephrine and related sympathomimetic amines (*see* Orth and coworkers, 1939). Arrhythmias due to ether are more likely to occur early in the course of anesthesia whereas arrhythmias due to cyclopropane are more likely to occur in deeper planes of anesthesia (Table 2).

Chloroform. The effects of chloroform on the heart and circulation differ markedly from those of ether. With the onset of surgical anesthesia induced by chloroform, the blood pressure gradually and continuously declines. At the end of one hour, the pressure may reach such a low level that anesthesia can no longer safely be continued. Cardiac output is uniformly decreased by chloroform anesthesia whereas it is significantly increased when ether is used (Blalock, 1927, 1928). Even under the most favorable circumstances, chloroform cannot be used for much longer than one hour. Three factors are involved in the cardiovascular action of chloroform. Chloroform causes a direct depression of the vasomotor centers and, as a result, peripheral vessels are dilated, especially those in the splanchnic area. Chloroform also has a direct depressant action on the musculature of blood vessels. Lastly, chloroform is directly depressant to the myocardium. The heart muscle is further injured by anoxia due to depression of respiration and progressive hypotension.

With the approach of the paralytic stage of anesthesia, the blood pressure is therefore quite low. Although the effects of vasomotor paralysis and cardiac incompetence dominate the circulatory picture until death, the heart remains beating after respiration has ceased. The heart beat is quite feeble and despite the fact that breathing actually stops first, functionally the circulation fails before the respiration.

Ventricular Fibrillation from Chloroform. Sudden syncope due to cardiac arrest may occur during the induction phase of chloroform anesthesia, particularly when administration is faulty or surgical maneuvers are started before anesthesia is sufficiently deep. For many years it was believed that the asystole was vagal in origin, but it is now known that ventricular fibrillation is the cause. The fundamental experiments in this field were performed on animals by Levy (1911, 1913, 1914) who demonstrated that chloroform sensitizes the heart so that it is more susceptible to factors precipitating ventricular arrhythmias and fibrillation. He found that fatal ventricular fibrillation could be induced in animals under light chloroform anesthesia by the injection of epinephrine, and that vagal resection and atropinization were not preventive measures. Levy also demonstrated that deep anesthesia offered protection against arrhythmia and that ether never precipitated ventricular fibrillation.

Sudden death during the induction phase of chloroform anesthesia is the most common type of cardiac accident noted when this agent is used. The clinical diagnosis can be made only if the anesthetist has his fingers on the pulse of the patient at the moment the arrhythmia occurs. A sudden decrease in cardiac rate from normal to zero "between two heart beats" is presumptive evidence of ventricular fibrillation. Several factors may combine to cause the fatal fibrillation. Irritation of the upper respiratory passages may initiate a trigeminocardiac reflex mediated from the brain stem through the spinal cord and stellate ganglia to the heart by way of the cardiac sympathetic nerves. This tends to cause ventricular tachycardia and extrasystoles. The discharge of epinephrine from the adrenal medulla due to fear or painful stimuli may act on a chloroform-sensitized myocardium to precipitate arrhythmia. The direct action of chloroform on the myocardium reduces the refractory phase of heart muscle, increases the irritability of the ventricle and lowers the threshold for the deleterious effects of epinephrine and sympathetic nerve impulses. Stimulation of the stellate ganglia in animals under light chloroform anesthesia, for example, will cause ventricular fibrillation. Lastly, an increased tension of carbon dioxide in the blood enhances the possibility of chloroform-induced fibrillation of the ventricles. Due to the irregular respiration and periods of apnea of a stormy induction, both high carbon dioxide and high chloroform concentrations are apt to coincide.

Although chloroform causes ventricular fibrillation much more readily than does any other anesthetic agent, ethyl chloride is also capable of initiating the arrhythmia. Even when clinical observation of the patient under chloroform anesthesia reveals no abnormalities of cardiac function, electrocardiographic evidence of ventricular irregularities may be seen. Hill (1932) restudied the effects of chloroform on the human heart and has confirmed clinically the aforementioned experimental findings of Levy. About 50 per cent of all persons under chloroform anesthesia manifest the ominous type of multiple focus ventricular tachycardia (Figure 5) which precedes ventricular fibrillation. The disturbance is transient, disappears as anesthesia deepens, and is not detectable clinically.

Gastro-intestinal Tract. *Nausea and vomiting* appear especially during recovery from anesthesia, but may occur during induction. The mechanism is central rather than local, but may be due in part to irritation of the stomach from swallowed vapors of ether or chloroform. Postoperative vomiting is a complication which may prove harmful and which the surgeon attempts to avoid by careful selection of the anesthetic. With ether, the incidence of nausea or vomiting approximates 57 per cent, as reported by Waters (1936) from a study of 10,600 administrations of anesthesia. In this same series, the incidence of nausea or vomiting for other agents was as follows: cyclopropane, 39 per cent; ethylene, 33 per cent; nitrous oxide, 23 per cent.

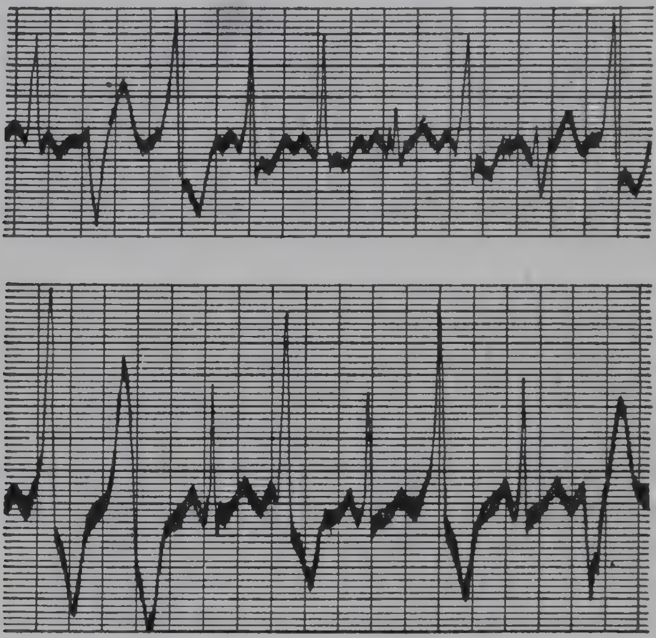

FIGURE 5. *The effect of chloroform anesthesia on the human heart as noted in the electrocardiogram.*

Upper tracing: Lead II, male, aged 56. Seventeen minutes after the induction of chloroform anesthesia, the heart rate is 142 per minute and no normal ventricular complexes are evident. All complexes are ventricular extrasystoles of diverse origin. Rhythmic P-waves are visible before many of the ventricular beats.

Lower tracing: Lead II, female, aged 38. Twenty-six minutes after the induction of chloroform anesthesia, the heart rate is 128 per minute and multiple extrasystoles from both ventricles are present. (After Hill, 1932. Courtesy of the *Edinburgh Medical Journal.*)

Gastro-intestinal tone and movements are considerably inhibited during and for varying periods after surgical anesthesia with ether and chloroform. This may be due to a peripheral action of the anesthetic agents on smooth muscle and its intrinsic autonomic innervation (Miller, 1926). Chloroform is more depressant in this regard than ether. Postanesthetic dilatation of the stomach occurs to some degree in nearly all cases; but occasionally acute and marked dilatation of the stomach may follow general anesthesia. This is a grave complication which necessitates early diagnosis and urgent treatment. The gastro-intestinal atony which follows abdominal operations is only in part the result of the anesthetic. It arises in no small measure from handling of the viscera during operation. Preanesthetic medication with morphine tends to counteract the depression of the gastro-intestinal musculature caused by anesthesia, but atropine nullifies this action of morphine to some degree.

The incidence and severity of postoperative intestinal ileus vary with the type and duration of anesthesia and the nature of the operation. In the series of anesthetic administrations studied by Waters (1936), to which reference has been made, ether caused postoperative distention in 16.5 per cent of 2400 cases. The incidence for other anesthetic agents was as follows: cyclopropane, 13.5 per cent of 5900 cases; ethylene, seven per cent of 1000 cases; nitrous oxide, three per cent of 1300 cases. Usually the small intestine recovers its normal motility within 48 hours after anesthesia. The colon, on the other hand, recovers within a few hours and becomes quite spastic. This results in the accumulation of gas and fluid in the small bowel. Various drugs, including posterior pituitary solution, physostigmine, prostigmine, mecholyl and other choline esters, in addition to enemata and rectal tubes, are used to stimulate peristalsis and relieve the pain of gaseous distention.

Urinary Tract. In man, the flow of urine steadily diminishes during anesthesia with chloroform; this is associated with a declining blood pressure. Urinary flow is also diminished when ether is used, perhaps because of renal circulatory changes or the anhydremia which accompanies ether anesthesia (Barbour and Bourne, 1924). Both ether and chloroform produce some degree of renal irritation but this is more pronounced with chloroform. The incidence of postanesthetic albuminuria is variable. Casts are occasionally found in the urine after anesthesia with either agent. Chloroform anesthesia may be followed by glycosuria due to hyperglycemia. Phenolsulfonphthalein excretion tests indicate a slightly lowered renal function during and for a day or two after ether anesthesia. Renal irritation occurring after ether is transient in patients with normal kidneys. In patients with chronic nephritis, however, serious exacerbations of the disease may result. Chloroform is the more serious offender. To cite but one example, in animals with experimental uranium nephritis, chloroform anesthesia is quite toxic, but ether anesthesia is relatively innocuous (MacNider, 1913). Injury to the kidney arising from chloroform is evident mainly in the tubular epithelium. The effects of anesthesia on the kidney have been reviewed by Mousel and Lundy (1940).

Postoperative retention of urine is fairly frequent after chloroform and ether anesthesia and may require catheterization or the use of drugs to stimulate the atonic urinary bladder.

Uterus. During parturition, uterine activity is only slightly influenced by light anesthesia which is employed intermittently to coincide with the periods of pain. Obstetrical analgesia sufficient to control labor pains may be obtained with a depth of anesthesia which does not interfere with the progress of labor. The use of ether presents some difficulty because of the time interval necessary for induction of ether analgesia. Unless the pains are anticipated, the analgesic effects of the ether may come only after the pain has developed. Ether, however, is very safe and the amnesia for pain which follows each interval of its administration does much to relieve the ordeal. Ether may also be given rectally in oil for obstetrical analgesia and amnesia (Gwathmey and McCormick, 1935). Chloroform is more rapid in action and therefore quickly produces obstetrical analgesia, but is unsafe to use because of its toxic effects on the liver.

During the second stage of labor, ether anesthesia is often employed for normal delivery or low forceps extraction. When properly given to the depth of lower plane i, ether is safe and does not seriously interfere with the forces of labor or the respiration of the infant. With deeper anesthesia, uterine contractions are somewhat slowed and weakened, and labor prolonged. Maximal relaxation of the uterus does not occur until plane iii is reached. All volatile anesthetics easily pass the placental barrier and thus reach the same concentration in the fetal circulation as in the maternal blood.

Metabolic Effects. Most workers are agreed that general anesthetics tend to reduce the serum bicarbonate and pH of the blood. This occurs especially in prolonged anesthesia, and chloroform causes the greatest decrease. The bicarbonate is displaced partly by chloride and partly by an unidentified acid (Austin and coworkers, 1924), possibly phosphoric acid (Stehle and Bourne, 1924) or lactic acid (Ronzoni and coworkers, 1924). Acetone bodies may also appear in the urine after ether or chloroform anesthesia, especially the latter. In diabetes mellitus chloroform anesthesia is particularly dangerous.

Hyperglycemia is a frequent accompaniment of general anesthesia and occurs especially during induction. The blood sugar may rise to a level two or more times higher than normal. Hyperglycemia is probably due to increased glycogenolysis in the liver or to an inhibition of the action of insulin; but the exact mechanism is not settled. The liver glycogen falls coincident with the blood sugar rise. The elevation in blood sugar is markedly reduced by section of the hepatic nerves or by adrenalectomy (Phillips and Freeman, 1933). Hyperglycemia due to ether anesthesia is probably related especially to the secretion of epinephrine and stimulation of the sympathetic nerves to the liver; but a small residual rise in blood sugar occurs during ether anesthesia in completely sympathectomized animals. The elevation of blood sugar after chloroform is more marked and more prolonged than after ether, and may be due in part to a direct action of chloroform on liver cells (Ravdin and coworkers, 1938). As a rule, normal blood sugar levels are again reached within 24 hours after anesthesia.

Liver Damage by Chloroform. Chloroform, like certain other halogenated hydrocarbons, is capable of causing cirrhosis of the liver if given in small repeated doses. The prolonged administration of chloroform anesthesia results in acute fatty degeneration of the liver, and the kidney, heart, and other parenchymatous organs are likewise damaged. Within a few days after chloroform anesthesia, there may develop severe prostration, protracted nausea and vomiting, jaundice and coma. This syndrome, which has been called "delayed chloroform poisoning" and "postanesthetic toxemia," often results in death. It is practically never seen after ether. The upper time limit for safety as regards the liver is about 45 to 60 minutes of chloroform anesthesia, a limit also imposed by the fall in blood pressure caused by this agent. Chloroform is absolutely contraindicated as an anesthetic in patients with hepatic disease and may be said always to injure the liver.

The symptoms of delayed chloroform poisoning develop from the first to the third postoperative day. Thus there may be an asymptomatic interval after recovery from anesthesia. The course of the illness is somewhat similar to that of phosphorus poisoning, because in both are seen the blood, urinary and metabolic changes associated with severe toxic hepatitis or acute yellow atrophy. Jaundice, increased serum bilirubin, bile in the urine, reduction in liver function, increased nitrogen excretion, lowered blood fibrinogen and the appearance of leucine and tyrosine in the urine are some of the more prominent findings. The hemorrhagic tendency which occurs is due to the failure of prothrombin formation by the injured liver (see page 1296). Death usually occurs on the fourth or fifth day, and autopsy reveals degeneration and necrosis of liver tissue most marked around the central veins—a finding typical of chloroform poisoning. Recovery occurs without residual liver damage.

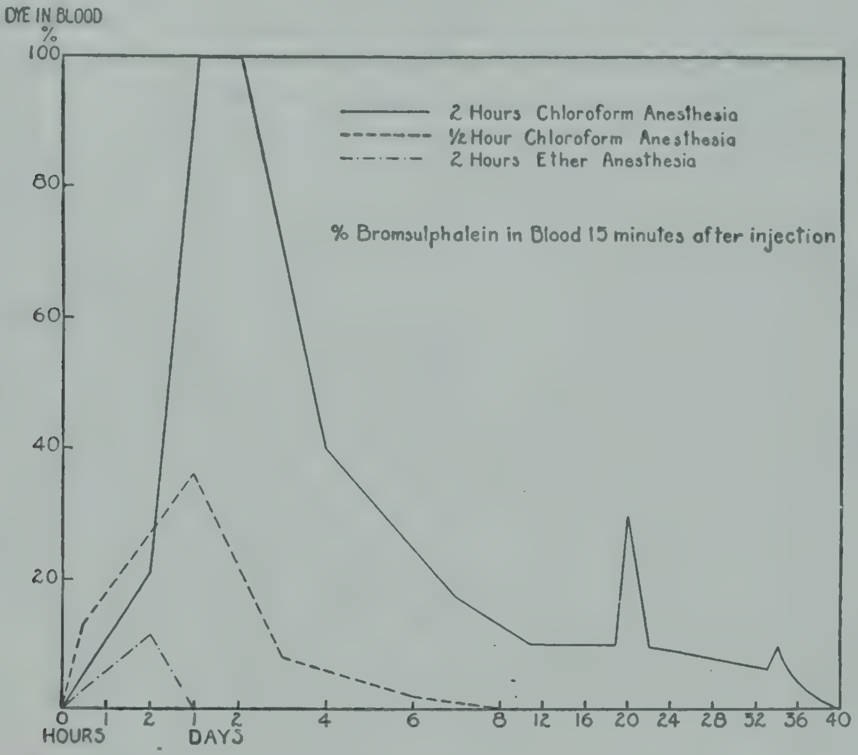

FIGURE 6. *The effect of chloroform and ether anesthesia on the hepatic function of dogs as measured by bromsulfalein dye excretion tests.*

Control figure at zero time. Before anesthesia the liver removes all the injected dye from the circulation within 15 minutes. Observe that only 30 minutes of chloroform anesthesia cause functional impairment of the liver detectable for eight days; two hours of chloroform anesthesia, for 40 days. In contrast, ether anesthesia for two hours causes only slight alteration in hepatic function, no longer evident after 24 hours. The secondary rises occurring late in the two-hour chloroform curve are associated with lipemia. Note the change in time scale. (After Rosenthal and Bourne, 1928. Courtesy of *The Journal of the American Medical Association.*)

The experiments of Rosenthal and Bourne (1928), in which bromsulfalein was used to study the effects of anesthesia on the hepatic function of dogs, show clearly the differences between chloroform and ether. The livers of normal dogs excrete into the bile nearly 100 per cent of the intravenously injected dye within fifteen minutes. When chloroform anesthesia is given for only one-half hour, impaired elimination of dye is detectable for eight days. If the chloroform is administered for two hours, impairment of dye excretion lasts for six weeks. On the other hand, full ether anesthesia causes only slight retention of dye, and excretion is quite normal on the second postanesthetic day (Figure 6). These functional tests are quite sensitive and correlate well with the known histologic changes seen in the liver after varying periods of inhalation of chloroform. Even after several hours of ether anesthesia, cytological evidence of liver damage is not apparent.

The hepatic changes induced by chloroform can be prevented in some measure by a high carbohydrate, high protein and low fat diet prior to anesthesia and by avoiding anoxia. Conversely, starvation and a high fat diet render the liver more susceptible to damage, and anoxia increases the injury caused by chloroform. Liver glycogen probably offers in itself no specific protection but rather insures, when it is plentiful, a concomitant absence of fat in the liver cells. It may also exert a "protein-sparing" action. The best protection appears to be afforded by a plenitude of protein stored in the liver (Goldschmidt, Vars and Ravdin, 1939).

Miller and Whipple (1940) also have emphasized the rôle of adequate protein stores in the body in protecting against liver damage by chloroform. For example, they have shown that 15 to 20 minutes of chloroform anesthesia in dogs depleted of protein (by low protein diet alone or combined with bleeding or plasmapheresis) is frequently fatal and causes extensive hyaline necrosis of the liver and the typical picture of chloroform poisoning. Control experiments in dogs without protein depletion indicated that 90 minutes of chloroform anesthesia could be tolerated with but little liver injury. That protein is also protective against hepatotoxic agents other than chloroform is suggested by the experiments of Messinger and Hawkins (1940) who found that liver injury produced by arsphenamine in dogs fed a protein diet was trivial and promptly repaired. A carbohydrate diet was somewhat less beneficial than protein in this respect and fats proved markedly deleterious. Also, fat-fed animals with severe intoxication induced by arsphenamine showed definite improvement when the fat diet was changed to protein. It is thus clear that the older concept concerning the protective action of carbohydrates on the liver must be modified to include protein. It is also suggested by the experiments cited that, in the face of established acute liver injury, a diet of protein as well as carbohydrate may prove of value. The mechanism by which protein protects the liver requires elucidation, but it has been suggested that protein may exert a direct protective action on liver cells or allow rapid regeneration of liver tissue, *pari passu* with injury (*see* discussion of Goldschmidt and associates, 1939).

Blood. The acetonemia, reduction in plasma bicarbonate, and the hyperglycemia incident to general anesthesia with ether and chloroform, as well as the marked alterations occurring in chloroform poisoning, have already been mentioned. The *formed elements* of the blood are not directly affected by ether anesthesia, but the red and white blood cells and hemoglobin values may be secondarily altered by changes in *plasma volume* and many other factors incident to the anesthesia and operative procedure, including a reduction in the size of the spleen. Ordinarily there occurs some reduction in plasma volume and this, combined with contraction of the spleen, causes a proportionate rise in blood viscosity, red blood cell count and hemoglobin (Barbour and Bourne, 1923; Searles and Essex, 1936; Bollmann, Svirbely and Mann, 1938; Searles, 1939). Stewart (cited by Beecher, 1938), employing the Gregersen dye method, found that during ether anesthesia in man the plasma volume diminished nearly 15 per cent, concomitant with an increase of extracellular fluid volume of over seven per cent. McAllister (1938) has observed a similar reduction of plasma volume in dogs under ether anesthesia.

Coagulation time may be shortened by ether anesthesia (Searles, 1939), but is apparently unaffected by chloroform. Although *hemolysis* of red corpuscles by ether and chloroform can be observed in the test tube, the phenomenon is not seen with the low concentrations necessary for anesthesia. It certainly has not been definitely proved that ether or chloroform hemolyzes red blood cells during clinical anesthesia, as is believed by some. If the patient's hemoglobin value is below 50 to 60 per cent, however, general anesthesia may be an unsafe procedure. A poor hemoglobin content of the blood makes the patient a poor surgical risk. General anesthesia, especially with chloroform, introduces the elements of asphyxia, low blood pressure, and possible damage to red blood cells, all of which are undesirable factors in an anemic individual. The relation of anemia to the appearance and detection of cyanosis is discussed on page 83.

The *white blood cells* are increased in number during ether anesthesia; this causes a rather striking polymorphonuclear leukocytosis. The total number of leukocytes may be increased two- or three-fold and may not return to normal levels for three or more days. These alterations are not peculiar to ether anesthesia, but also occur with other general anesthetic agents, particularly cyclopropane. The mechanism is not fully understood.

Absorption, Fate and Excretion. Ether and chloroform are absorbed almost instantaneously from the pulmonary epithelium, and both are excreted almost quantitatively by the same channel. The total amount absorbed and the rate of excretion are discussed in the following section. The diffusion of the volatile anesthetic agents into and out of the body is purely a physical process, and follows the laws of the passage of water-soluble vapors and gases across permeable membranes.

More chloroform is carried in the blood by the red corpuscles than by the plasma (McCollum, 1930). It is apparently loosely combined with cell lipids. Ether, on the other hand, is more equally distributed between plasma and cells.

Ether is not oxidized in the body, and over 90 per cent of it can be recovered in the exhaled air. Chloroform, on the other hand, is decomposed to a limited extent by the tissues but the degree of this decomposition is practically negligible. A small fraction of both ether and chloroform is excreted in the urine, milk, sweat and other body fluids. The fraction of ether not found in the expired air can be accounted for by extrapulmonary excretion.

Upon discontinuance of anesthesia, the amount of ether and chloroform in the blood is reduced by half within five minutes. The elimination of the remainder is naturally much slower. Traces of ether can be detected two hours after the cessation of anesthesia, but after four hours this is no longer possible. The inhalation of carbon dioxide greatly enhances the rate of excretion of the anesthetic (Figure 7). When chloroform is used, traces are detectable seven hours after anesthesia has ceased and often for as long as twenty-four hours.

General Principles Governing the Transfer of Anesthetic Vapors and Gases. In the last analysis, the degree of anesthesia depends on the concentration of anesthetic agent in the tissues of the central nervous system. This in turn depends on the concentration in the blood, and the latter is controlled by several factors, particularly the anesthetic concentration in the inspired air. The factors controlling the onset and maintenance of surgical anesthesia with ether and chloroform apply as well to all the anesthetic vapors and gases, and the description to be given here does not differ in any important respect for any particular agent.

Five conditions are involved in passage of the anesthetic from the container into the patient's central nervous system (Guedel, 1937). These are as follows: (1) the partial pressure of the anesthetic in the inspired air; (2) the respiratory minute volume; (3) the permeability of the alveolar membrane; (4) the circulation velocity through the lungs; (5) the circulatory volume to different tissues of the body. These factors and their bearing on induction and depth of anesthesia may now be considered.

(1) *Partial Pressure of the Anesthetic Agent.* As previously stated, the anesthetics exist in the blood and body fluids mainly in physical solution and obey the laws governing

the absorption of gases by fluids. The alveolar membrane allows the free passage of volatile anesthetic agents in both directions, and the diffusion is always in the direction of the lower concentration, that is, the lower partial pressure. When anesthesia is first induced, the absorption into the blood is quite rapid because there is a steep concentration gradient downward from the alveolar air to the blood. As anesthesia is continued, this gradient naturally becomes less steep because the blood and tissues are approaching equilibrium with the alveolar air. The diffusion rate is therefore slower. When equilibrium is finally obtained, the diffusion gradient has practically disappeared because the partial pressures of the anesthetic in the tissues and inspired air are nearly equalized, at which point diffusion almost stops. The reverse process occurs when the administration of anesthesia ceases. The air in the lungs now contains a very low partial pressure of the anesthetic, and the diffusion gradient is therefore outward from the tissues to the exhaled air. At first, this outward diffusion gradient is steep, allowing rapid excretion and emergence from anesthesia. As the concentration gradient becomes less steep, diffusion proceeds more slowly. The final elimination of anesthetic, therefore, is quite slow.

The partial pressure of the anesthetic vapor in the inhaled air is of much greater importance in determining speed of induction and depth and safety of anesthesia than is the absolute amount of anesthetic used (Haggard, 1924). To illustrate this point, the fact may be recalled that it is common experience to see one patient inhale and again exhale many ounces of ether in the course of a prolonged operation, without obtaining deep anesthesia; on the other hand, a second patient may be rapidly precipitated into dangerously deep anesthesia by inhaling only a few cubic centimeters of the same anesthetic given as a concentrated vapor.

(2) *Respiratory Minute Volume.* The speed of induction and emergence also depends on the respiratory minute volume. The difficulty of induction due to morphine-induced respiratory depression has been described (page 37). Respiratory depression not only decreases the amount of anesthetic inhaled per unit of time, but also, if breathing is shallow, lessens the extent of the alveolar surface exposed to the anesthesia. Conversely, if respiration is made deeper or faster, as occurs when carbon dioxide is administered, diffusion is enhanced and induction or emergence is speeded (Figure 7).

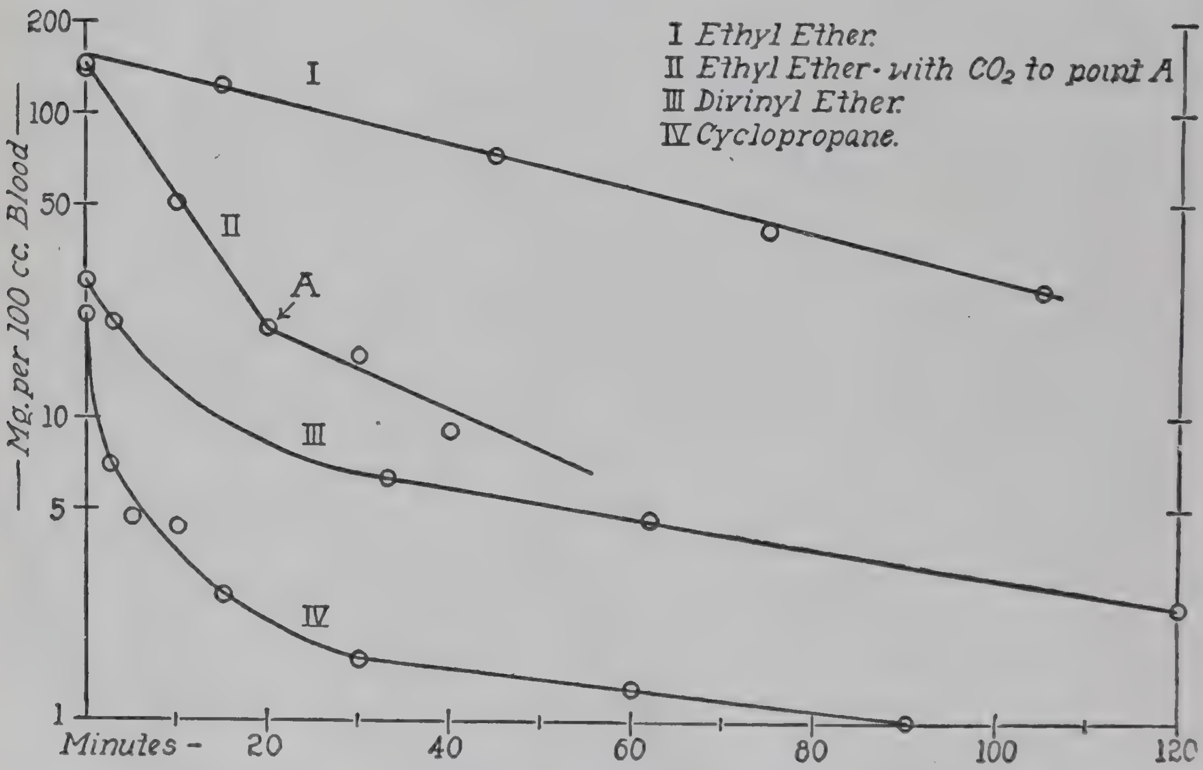

FIGURE 7. *The elimination of anesthetics from the blood.*

Experiments performed on dogs; blood concentration of anesthetics plotted on a logarithmic scale against the time in minutes. Note the more rapid initial excretion of divinyl ether and cyclopropane in comparison with ethyl ether. Observe also that the inhalation of carbon dioxide hastens the elimination of ether from the blood at the termination of anesthesia. (After Ruigh, 1939. Courtesy of the *Proceedings of the Society for Experimental Biology and Medicine.*)

(3) *Permeability of the Diffusion Surface.* The diffusion rate of anesthetics into the blood depends not only on the partial pressure of the gas and the respiratory minute volume, but also on the ability of the alveolar membrane to allow the ready passage of the gas through it. Ordinarily, the alveolar membrane allows free diffusion of gases in both directions. The usual feature encountered in clinical anesthesia which tends to alter the permeability of the normal aveolar membrane is the secretion of mucus. Obstructed alveoli offer an appreciable obstacle to the passage of gases, and higher partial pressures of anesthetic vapors are then needed to obtain the same speed of onset and depth of anesthesia.

(4) *Circulation Velocity.* The circulatory velocity of the blood is not particularly important under most circumstances, except in regard to the rapidly acting anesthetics such as nitrous oxide, ethylene and cyclopropane. Even then, it determines only the speed of induction. All the blood of the body is said to pass through the lungs in slightly more than one minute, and at least one and usually two such circuits must be made in the presence of high partial pressures of the gases before full brain saturation and surgical anesthesia can occur.

(5) *Rate and Volume of Blood Flow through the Brain and Other Tissues.* The abundant blood supply of the brain assures that this organ becomes saturated with the anesthetic more quickly than do other tissues of the body, because the rate of blood flow through an organ bears a direct relation to the speed of saturation (Haggard, 1924). The fat depots of the body are the last to reach anesthetic equilibrium because of their poor blood supply, and adipose tissue may contain little anesthetic at the time when the concentration in the brain is such that surgical anesthesia has already occurred. Under these circumstances a second diffusion gradient is established between the brain and other tissues. During short operations with the rapidly acting anesthetics, when anesthesia is discontinued there are thus two gradients along which the brain loses the anesthetic—one extending to the lungs and the other to the tissues. The various organs and tissues of the body may be viewed as a huge buffer system which acts to retard the induction of anesthesia, to hasten elimination of the anesthetic from the brain (under such a special circumstance as mentioned above) and to retard its final elimination from the body (Haggard, 1924). On the other hand, the buffer system serves to retard emergence from anesthesia which has been maintained sufficiently long so that the buffer tissues are saturated.

Concentrations of Ether and Chloroform in the Blood and Inspired Air. The clinical data available on the concentration of anesthetic in the blood and inspired air during different depths of anesthesia are still not complete. Most of the information has been obtained from experiments on animals, and some of the discrepancies reported arise from the difficulties in judging depth of anesthesia. Another factor of importance is the source of blood on which determinations are made. For example, during induction, the concentration of anesthetic in the venous blood coming directly from an organ is the only index to the degree of saturation. The following figures should therefore be taken as approximations which are serviceable chiefly for comparing ether and chloroform.

Ether. Induction of anesthesia requires a concentration of ether vapor in the inspired air of from five to seven volumes per cent. This amounts to from 15 to 21 mgm of ether in every 100 cc of air. As the desired plane in stage III is reached, the concentration is gradually reduced to four or five volumes per cent. The anesthetist naturally does not stop to analyze the concentration of ether under the mask but depends upon the rate of ether administration and the response obtained to guide him. If the inhalation of five or six volumes per cent of ether is continued sufficiently long, respiratory failure ultimately ensues. Higher concentrations (10 to 11 volumes per cent) cause death more rapidly. The concentration of ether in the blood at the time of respiratory arrest is about 150 to 170 mgm per cent. The blood levels for the different planes of stage III are approximately as follows: plane i, 110 mgm per cent; plane ii, 120 mgm per cent; plane iii, 130 mgm per cent; plane iv, 140 mgm per cent.

Chloroform. Anesthesia with chloroform is accomplished with much lower concentrations of this agent in the blood and inspired air than are needed with ether. Surgical anesthesia can be obtained with 1.5 volumes per cent (7.5 mgm per cent) in the inhaled air. This is one-third that required for ether. The breathing of two volumes per cent of chloroform for any extended period proves fatal. The blood concentration at death is between 40 and 60 mgm per cent. Inasmuch as the difference between the anesthetic and fatal concentrations of chloroform in the air is only 0.5 per cent, the margin of safety in this regard is narrow. When one also considers the time factor imposed on chloroform anesthesia by the fall in blood pressure and the danger of liver damage, the great superiority of ether over chloroform is at once evident.

The concentrations of ether and chloroform in the blood and inhaled air necessary for different levels of anesthesia are indicated in Table 1 (Buckmaster and Gardner, 1907; Haggard, 1924; Robbins, 1935, 1936).

Table 1

CONCENTRATIONS OF ETHER AND CHLOROFORM IN THE BLOOD AND INHALED AIR

CONCENTRATION IN BLOOD

	Chloroform mgm %	Ether mgm %
Light anesthesia	25–30	100–110
Deep anesthesia	30–40	130–140
Respiratory failure	40–70	160–170

CONCENTRATION IN INHALED AIR

	Chloroform volumes %	Ether volumes %
Not sufficient for anesthesia	0.5–0.7	1.5–2.5
Light anesthesia producible after prolonged inhalation	1.0	3.0–3.5
For maintenance of surgical anesthesia	1.5	4.0
Respiratory arrest	2.0	7.0–10.0

Contraindications. *Ether* is naturally to be avoided when general anesthesia as such is contraindicated. In acute respiratory infections and in chronic pulmonary diseases such as tuberculosis, bronchiectasis, etc., ether is not desirable due to the bronchopulmonary irritation and stimulation of secretion which it causes. It is also best not employed in patients with advanced renal disease. Where an open flame or actual cautery is in use, ether is dangerous unless special precautions are observed.

Chloroform, although it has the advantages over ether of affording more rapid induction, less excitement and pulmonary irritation, less postoperative nausea and vomiting, and greater muscular relaxation, possesses no indispensable advantages which can offset the dangers incident to its use. It has been estimated that ether causes one death in 16,000 anesthesias, whereas deaths from chloroform occur nearly five times as frequently. Chloroform is particularly contraindicated in patients with hepatic, cardiac and renal disease, and also in those with anemia, acidosis, or diabetes. Chloroform is still used in the tropics where ether is often difficult to administer by the open drop method because of its high volatility.

Tolerance and Idiosyncrasy. It is generally stated that there is a cross-tolerance between alcohol and the methane series of anesthetics. This is particularly manifest during the induction period. It is common knowledge, for example, that addicts to alcohol are hard to anesthetize, but this is less difficult with chloroform than with ether. Morphine addicts are also said to be relatively insusceptible to the anesthetic action of ether. Patients with hyperthyroidism often react badly unless proper preanesthetic medication has been given. Contrary to general opinion, fat people do not require more anesthetic than non-obese persons of equal weight. Despite the affinity of ether and chloroform for lipids, little anesthetic agent reaches fat depots due to their poor blood supply.

Explosiveness. Chloroform is not inflammable. Inasmuch as ether is the anesthetic most frequently used, many explosions and fires have occurred because of it. The accidents are not serious as a rule when the open method of ether administration is used. Ether vapor is more than twice as heavy as air and is carried downward to the floor of the operating room. If an open flame is absolutely necessary during the use of ether by the open method, it should be placed at least 18 inches above and the same distance to the side of the ether mask. The closed method is safer if an open flame cannot be avoided. The introduction of the closed method, however, has made ether explosions much more serious because of the employment of oxygen which promotes the rapid propagation of ether flames and violent detonation. Mixtures of nitrous oxide and ether are practically as dangerous as those of oxygen and ether. If the flames reach the lungs of the patient, the tissue may be so burned that death ensues, or the explosion may rupture the lungs. The cautery should not be used about the head or neck of a patient under ether anesthesia. It is permissible on other parts of the body only if the Trendelenburg position is employed (so that the cautery is higher than the ether), provided the usual screen is in place and all air currents are avoided.

When ether anesthesia is discontinued at the end of an operation, the exhaled air of the patient is probably still inflammable for from 10 to 15 minutes. During prolonged ether anesthesia, the body cavities and tissues contain explosive concentrations of the chemical. For example, the use of the cautery on fatty tissue may cause a local flame. Anesthetic gases may also find their way into the air bubble of the instrumented bladder and explode when ignited by the spark of a fulguration apparatus.

Miscellaneous Uses of Ether

Ether has been employed as a *local anesthetic* on the skin in the form of a spray, in the same manner as ethyl chloride. Ether, if rubbed on the skin, produces a *rubefacient action* similar to that of alcohol or chloroform. It is less irritant than chloroform, however, because it evaporates more quickly. Occasionally, ether is used in superficial wounds as an *antiseptic* and *cleansing solvent*. Ether has been given in small doses orally as a *stomachic* and *carminative,* in the form of *Spirits of Ether* (*Hoffmann's Drops*), N.F., or *Compound Spirit of Ether* (*Hoffmann's Anodyne*), N.F. The dose of either is four cc. Ether is sometimes used as an *expectorant* in cough medicines. A final use of ether is for its *"stimulant" action* in cases of fainting or collapse. For this purpose, it may be combined with aromatic spirits of ammonia or injected subcutaneously in one cc quantities. Any action that ether may exert under these circumstances is purely one of reflex sensory stimulation. The administration of ether in olive oil or caoutchouc (latex) by rectum, as used by some for obstetrical analgesia, is also of value in some cases of *status asthmaticus* which have become refractory to all ordinary therapeutic measures, including epinephrine.

Miscellaneous Uses of Chloroform

Chloroform is employed as a *rubefacient* or *counterirritant* in liniments, such as *Chloroform Liniment,* U.S.P. *Chloroform Water,* U.S.P., B.P., is sometimes prescribed orally in four cc doses as a *carminative*. This preparation is also used as a *vehicle* for cough medicines and sedatives.

For the production of *obstetrical analgesia* chloroform is still used in deliveries performed in the home or in out-of-the-way communities where skilled assistance is not available. Relief of pain is obtained by the inhalation of two cc (one-half teaspoonful) of chloroform poured on cotton or blotting paper which is then placed in the bottom of a drinking glass held in the patient's hand. Effective analgesia is obtained by a very few inhalations. No opportunity for complete anesthesia exists because as soon as stage II appears consciousness and muscular coordination cease. The hand drops, automatically ending the administration. As consciousness clears and pain returns, the patient resumes the inhalation. Analgesia may last for 20 minutes or more after one such treatment. The method is said to be relatively safe and has also been used for relief during the changing of painful dressings. The danger of entering the delirium stage and of precipitating ventricular fibrillation appears too great to recommend the use of this form of inhalation anesthesia.

DIVINYL ETHER

Historical. Divinyl ether is also called *vinyl ether, vinethene* and *divinyl oxide.* It was introduced as an anesthetic at the suggestion of Leake and Chen (1930) who believed that this compound might combine the potency of diethyl ether with the rapidity of induction and low toxicity of ethylene. Ruigh and Major (1931) subsequently synthesized the first pure divinyl ether. Pharmacological studies of its properties soon followed (Leake and associates, 1933; Goldschmidt and coworkers, 1934), and numerous clinical reports have appeared concerning its use for surgical anesthesia.

Chemistry and Preparations. Divinyl ether has the following structural formula: $CH_2=CH-O-CH=CH_2$. The commercially available preparation is *Vinethene* (N.N.R.). This is a clear, colorless fluid possessing a slight ethereal odor and a faint purplish fluorescence. It is very volatile, more so than ether, and boils at 28 to 31 C. Divinyl ether is approximately as inflammable and explosive as ethyl ether.

Divinyl ether undergoes decomposition on exposure to light or air, or to minute amounts of strong acids. It is marketed in dark bottles and should be kept tightly stoppered in a cool place, and must never be used more than 24 hours after the bottle has first been opened. Chemically pure divinyl ether is so volatile that if used as such it is likely to cause moisture to freeze on the anesthetic mask or in the gas machine. To overcome both this disadvantage and that of rapid deterioration, vinethene contains 3.5 per cent absolute alcohol and 0.01 per cent of a non-volatile oxidation inhibitor, phenyl-alpha-naphthylamine.

Anesthetic Actions. Divinyl ether possesses the characteristic actions on the central nervous system of the methane series of anesthetics. Its high potency and rapidity of action, however, make it unique. Divinyl ether has an anesthetic power of 100 per cent in that it can produce Stage IV anesthesia without preliminary medication or asphyxia (Figure 4). Goldschmidt and coworkers (1934) estimate its relative anesthetic potency as compared to ethyl ether to be 7:1, and also conclude from animal experimentation that divinyl ether has a wider margin of safety. This fact is of little or no advantage in clinical anesthesia because divinyl ether is so potent and produces deep anesthesia so rapidly that a dangerous or lethal plane may easily be entered. Thus the hazard accompanying its use is actually greater than that with ethyl ether.

Anesthetic Concentrations. In man, surgical anesthesia with good abdominal relaxation requires 18 mgm per cent of divinyl ether in the blood, only one-seventh of the concentration necessary for ethyl ether. For extra-abdominal operations in which marked muscular relaxation is unnecessary, a blood level of 11 mgm per cent is sufficient. The lethal concentration in man is not known. In the dog, a species requiring 28 mgm per cent in the blood for full surgical anesthesia, the lethal concentration is 68 mgm per cent.

Induction. Induction of anesthesia with divinyl ether is smoother and more rapid than that obtainable with ether, chloroform, or nitrous oxide. Unconsciousness occurs in one-half minute to one and one-half minutes and muscular relaxation sufficient for laparotomy is obtained in two and one-half minutes. The incidence of excitement is low, less than 0.5 per cent, and no struggle is seen. So rapidly does induction occur that analgesia without unconsciousness is rarely observed. No laryngeal irritation or spasm complicates induction and the masseters usually relax promptly so that an airway may be inserted with ease.

Surgical Anesthesia. Surgical anesthesia occurs rapidly, two or three times as quickly as with ethyl ether. It is evenly maintained provided the anesthetist has had experience with divinyl ether and watches the patient closely. It must be re-emphasized that it is easy to pass from the level of surgical anesthesia to Stage IV with divinyl ether anesthesia. Under no circumstances, therefore, should the anesthetic be pushed.

The *physical signs* under anesthesia with divinyl ether differ somewhat from those observed with other inhalation anesthetics. The characteristic signs during induction and plane i can be recognized only with difficulty because of the rapidity of action. During surgical anesthesia, the respirations are more rapid and somewhat more shallow than normal. If an adequate airway is maintained, the color remains good. The eye movements do not cease as rapidly as with other anesthetics. Thus the abdominal musculature may be sufficiently relaxed for surgical procedures and yet the eyelids and eyeballs may still be moving as in lighter planes of anesthesia. Depth of anesthesia must be judged chiefly by the rate, amplitude and character of the respiration.

Blood Pressure and Respiration. The blood pressure may undergo a slight and transitory fall but soon returns to normal and remains there throughout the period of anesthesia. Divinyl ether has no deleterious effect on the cardiovascular system. The respiratory rate may be somewhat elevated. Lethal concentrations cause respiratory depression and arrest before cardiac failure takes place.

Muscular Relaxation. Muscular relaxation is approximately as complete with divinyl ether as with ethyl ether, and therefore sufficient for all general surgical purposes. Some surgeons claim that muscular relaxation is as complete as with chloroform. Uterine activity during labor is not inhibited by divinyl ether used for obstetrical analgesia (Bourne, 1935).

Salivation. Divinyl ether is less irritant to the respiratory passages than is ethyl ether, but causes an increase in salivation, due perhaps to chlorinated ether impurities, decomposition products, or the material which is added to inhibit oxidation. After atropine, salivation is considerably reduced, and any excessive secretion which occurs can be controlled by a second dose of atropine.

Recovery and Postanesthetic Period. Recovery from anesthesia is rapid, smooth and without excitement. When anesthesia lasts only one-half hour, complete recovery occurs in less than four minutes. The incidence of vomiting is exceptionally low, being less than two per cent. Respiratory complications are rare and divinyl ether apparently causes few postoperative pulmonary sequelae.

Vital Organs. The heart is unaffected by divinyl ether, which can thus be used in patients with cardiac disease. There is also freedom from renal irritation. The gastro-intestinal musculature is not markedly inhibited nor is uterine activity depressed.

The possible effects of divinyl ether on the *liver* represent the most serious toxic potentiality. It seems that postanesthetic central lobular necrosis of the liver similar to that caused by chloroform occasionally occurs, and in a study of several fatalities after divinyl ether, liver changes were noted in at least two cases. In a series of 2675 divinyl ether anesthesias (Ravdin and associates, 1937), three deaths occurred but these were in no manner related to the anesthesia or to any postanesthetic liver damage. In each of the few reported cases of damage to the liver, when the anesthetic could reasonably be blamed, there is evidence either of prolonged use of divinyl ether, excessive dosage, or coincidental anoxia. If these three factors are strictly avoided, there appears to be no danger of damage to the normal liver. Animal experiments show that divinyl ether is much less toxic than chloroform for the liver. In order to produce hepatic injury, divinyl ether must be given not only for a long period but also there must be an associated anoxia (Goldschmidt and associates, 1934, 1937). In addition to the prevention of anoxia by maintenance of a patent airway and an adequate concentration of oxygen at all times, it is also important that, if possible, a high carbohydrate, high protein and low fat diet be given prior to anesthesia (page 66). Obviously, patients known to have liver disease should not be anesthetized with divinyl ether. Cyanosis should be avoided and its appearance is a signal for the administration of oxygen and a change of anesthetics.

Methods of Administration. Divinyl ether may be given by the open drop method, the semi-open technic, or with any of the usual gas machines. For short operations, lasting not over one-half hour, the open drop method is employed and preferred. Either an open face mask or the simpler technic of fluffing several thicknesses of gauze and applying the latter directly to the nose is employed. Divinyl ether is dropped on the mask or gauze at the rate of 60 to 80 drops per minute for adults and older children, half this rate sufficing for infants. Too high a concentration of vapor should be avoided and an adequate airway should be maintained. If difficulty is experienced in obtaining or maintaining sufficiently deep anesthesia with the open method, a wet towel may be wrapped around the base of the mask or gauze in order to decrease dilution by air.

For operations lasting over one-half hour, a gas machine is employed, and divinyl ether is volatilized with pure oxygen. Not only is the anesthetic agent conserved, but of greater importance is the fact that an abundance of oxygen is assured. For operations lasting much longer than one hour, divinyl ether should not be used. If the operation lasts longer than contemplated and extends over the one and one-half hour limit of safety at present adopted for divinyl ether, another anesthetic agent should be substituted.

Advantages. Divinyl ether provides a pleasant and rapid induction and recovery. It produces the same degree of muscular relaxation obtainable with ethyl ether, but accomplishes this much more quickly and without the excitement, prolonged recovery, pulmonary irritation, postoperative vomiting and other objectionable features common to ethyl ether. Except for the slight possibility of liver damage already discussed, divinyl ether causes no untoward changes in the vital organs or metabolic functions of the body.

For operations of short duration when rapid induction and recovery must be combined with complete muscular relaxation, divinyl ether occupies a definite sphere of usefulness. It does not entail the anoxia of nitrous oxide anesthesia and gives much greater relaxation. Furthermore, it requires no cumbersome apparatus for short operations, and can thus be used in the ward and home or for ambulatory patients in the physician's office. Divinyl ether may also serve as an induction anesthetic for other agents, or to supplement nitrous oxide or ethylene anesthesia when additional muscular relaxation is needed. It has also been employed in combination with ethyl ether, the two fluids being mixed in the ratio of one part of divinyl ether to three parts of ethyl ether.

Indications and Special Uses. The advantages of divinyl ether enumerated indicate its usefulness especially for short operations when greater muscular relaxation is needed than is obtainable with the anesthetic gases, when speedier induction and recovery are required than is allowed by ether, or when no special apparatus is available. It has been employed under these conditions in a wide variety of major surgical procedures, either alone or as a supplement to nitrous oxide or ethylene.

In *dental surgery* and *exodontia*, divinyl ether has distinct advantages over nitrous oxide. It is more rapid than nitrous oxide both in induction and recovery, avoids anoxia, requires no gas machine, and provides a longer period for operation and more complete relaxation. While more experience will be needed to determine the status of divinyl ether in dentistry, there can be no doubt that in many cases it may prove helpful. In *ophthalmology* and in *ear, nose and throat surgery*, divinyl ether may be employed in a variety of operations, and also where local anesthesia may need re-enforcement. Examinations of the fundi and myringotomies in children, for example, can easily be performed under divinyl ether anesthesia. In *orthopedic surgery*, the agent can be employed for anethesia for the fluoroscopic reduction of fractures, and the manipulation of bones and joints where repeated anesthetizations may be needed. In traumatic cases without surgical preparation, divinyl ether is useful. For *changing painful dressings*, especially in children, a few drops of divinyl ether are extremely helpful and may improve the morale of the entire ward. Only gauze and the bottle of anesthetic need be taken into the room. *Induction of general anesthesia* is done routinely with divinyl ether in some clinics. It is more rapid and smooth for this purpose than nitrous oxide and the excitement period is practically eliminated. If *spinal anesthesia* begins to wear off before the operation is completed, divinyl ether may be used. In *obstetrical procedures* divinyl ether may be employed for short operations. It gives sufficient muscular relaxation for perineal and deep pelvic surgery. It cannot be used for obstetrical analgesia because it acts too rapidly and causes deeper anesthesia than is desirable.

Disadvantages, Contraindications and Precautions. The chief disadvantage of divinyl ether is that it is not safely used for operations lasting much over one hour. Salivation is more frequent, even after atropine, than with other anesthetics. The slight possibility of liver damage requires attention to the liver function and diet before lengthy operations, and special care is necessary to avoid anoxia and cyanosis during anesthesia. Divinyl ether is contraindicated in patients with liver disease or hepatic insufficiency. In patients with bronchopulmonary disease in whom the possibility of excess mucus or salivary secretion might be undesirable, divinyl ether should be used with caution. The drug should not be given to those in whom oxygen want may develop easily. Due to its extreme volatility, the use of divinyl ether at high altitudes may offer difficulties.

Precautions to be observed are never to "push" the anesthetic, to maintain sufficient oxygenation, to limit the time of use by the open method to one-half hour and by the closed method to one and one-half hours, and to observe the same care against fire and explosion hazards as is observed with ethyl ether. Above all, divinyl ether should be used only by those thoroughly familiar with its anesthetic properties and limitations. Divinyl ether is a new anesthetic, and its toxicity and exact position cannot yet be fully defined.

ETHYL CHLORIDE

Historical. Ethyl chloride was introduced into medicine as a local anesthetic. For centuries it was known that limbs long in contact with snow or ice became insensitive. James Arnott in 1849 first used cold routinely for anesthesia by applying an ice and salt mixture to the skin. Ten years later, Richet used the evaporation of ether from the skin for producing anesthesia. Ethyl chloride soon replaced ether because of its lower boiling point. Flourens (1847) was the first one to call attention to the general anesthetic properties of ethyl chloride. This observation was overlooked, however, until 1894 when a Swedish dentist, Carlson, while applying ethyl chloride to a patient's gums, noted that the patient fell asleep and that the teeth could be extracted without pain. Undoubtedly the vapor was inhaled. Ethyl chloride was then reintroduced into general anesthesia.

Chemistry. *Ethyl Chloride* (*Monochlorethane*), U.S.P. B.P., C_2H_5Cl, is a very inflammable, colorless and highly volatile fluid. Its boiling point is 12 to 13 C. The vapor has a peculiar ethereal odor and is sharp and sweet to the taste. Ethyl chloride is slightly soluble in water, less so in the blood, and readily dissolves in alcohol or ether. It is dispensed in special glass or metal tubes as a liquid under pressure for use in local anesthesia. The tubes have a pin-hole exit covered by a spring cap, which when opened allows the fluid to issue forth as a fine spray with some force. The tubes should be stored in a cool place.

Use as a Local Anesthetic. Ethyl chloride freezes tissues when it is used as a fine spray and allowed to evaporate from the skin. The tissues reach a temperature of −20 C. The tube is held about 12 inches from the skin and the spray is directed against the site for operation, the warmth of the hand causing the fluid to volatilize and be ejected from the tube. The tissues become white and frozen and the adjacent skin should be prepared with vaseline to insure against sloughing.

Disadvantages. Ethyl chloride has a limited field of usefulness as a local anesthetic. The process of thawing is painful. Dissection of frozen tissue is difficult. Furthermore, freezing injures cells, lowers resistance to infection, and delays healing. Finally, anesthesia rarely lasts more than from a few seconds to a minute, and if the operation requires a longer time than was anticipated, obvious difficulties ensue. Consequently ethyl chloride can be used only for such minor purposes as the incision of boils, whitlows, removal of splinters, etc. Its main value is a psychic one, to distract the patient so that a simple incision, which ordinarily would not require local anesthesia, can be made.

Use as a General Anesthetic. Ethyl chloride produces the characteristic actions of the methane series of anesthetics. The presence of chlorine probably contributes to its rapid and intense action, but renders the drug more dangerous than non-halogenated congeners.

Induction and Recovery. General anesthesia produced by ethyl chloride appears and disappears rapidly. Induction requires only one-half minute to one and one-half minutes, and recovery occurs in a few minutes after administration of the anesthetic ceases. Excitement and struggle are usually absent due to the rapid induction. The chemical is relatively non-irritating to mucous membranes of the respiratory tract and causes no sense of suffocation as does ether. After-effects are mild.

Anesthetic Concentrations. Surgical anesthesia can be maintained by inhaling slightly over two volumes per cent of ethyl chloride vapor. The blood concentrations of ethyl chloride necessary for surgical anesthesia in man are as follows: 20 mgm per cent for light anesthesia; 30 to 150 mgm per cent for deep anesthesia; 40 to 180 mgm per cent for respiratory arrest. It is obvious from these data that there exists a considerable overlap of anesthetic, toxic, and lethal concentrations.

Technic of Administration. In order to produce surgical anesthesia, ethyl chloride must be present in the inhaled air during induction in a concentration of four to five volumes per cent. This can be accomplished only by the use of a mask. Ethyl chloride can be sprayed on the mask, a wasteful procedure, or it can be used in smaller amounts as a fluid poured onto a semi-closed mask. By the use of a gas machine, ethyl chloride can be volatilized and employed as a gas.

Disadvantages and Dangers. Ethyl chloride is a halogen-containing hydrocarbon with the potentiality for damaging parenchymatous organs. Induction and recovery are so rapid that the danger signals are indefinite and even a trained anesthetist has difficulty in maintaining an even anesthesia. Muscular relaxation is incomplete at safe depths of anesthesia. Although ethyl chloride is less toxic than chloroform, ventricular fibrillation and sudden cardiac arrest may occur (Guedel and Knoefel, 1936).

TRICHLOROETHYLENE

Trichloroethylene (N.N.R.) is a rather pungent, sweet-smelling, clear, colorless, and volatile liquid, having the formula $CHCl{:}CCl_2$. It has been used for general anesthesia (Jackson, 1934) and although its principal actions are similar to those of other members of the methane series of anesthetics, it has no advantage or indication as a surgical anesthetic (Report of the Council, 1936).

Therapeutic Uses. Trichloroethylene is used as a solvent in industry where it has produced poisoning. During the World War of 1914–1918, it was noted by Plessner (1915) that some workers using trichloroethylene in the airplane industry developed a peculiar bilateral loss of sensation over the distribution of the fifth cranial nerve. Oppenheim suggested to Plessner that he use the drug therapeutically in *trigeminal neuralgia* for the relief of the severe paroxysms of pain characterizing this disease, and a number of patients so treated were benefited. Trichloroethylene is available in one cc sealed frangible glass tubes. The tube is broken, placed in the bottom of a tumbler and the vapor is inhaled until the odor disappears. A second tube may be used if incomplete relief is obtained from the first. This treatment of patients with trigeminal neuralgia may be repeated three or four times daily for several weeks. The results obtained have been reviewed by Glaser (1931) who reported 15 cases of his own and 177 in the literature. Complete relief was obtained in about 15 per cent of cases and partial relief in from 13 to 75 per cent. The attacks diminish both in severity and frequency. A later report by Horrax and Poppen (1935) on 90 cases of tic douloureux treated with trichloroethylene indicates that about one-half of the patients received sufficient benefit to allow postponement of surgical procedures for at least six months. The remaining patients were not relieved.

The *mechanism of action* of trichloroethylene in trifacial neuralgia is obscure. The facial anesthesia, which was first noted in industry and which led to the therapeutic use of the chemical, is not evident when trichloroethylene is employed clinically. It is possible that an impurity accounted for the anesthesia. The drug has no marked effect on neuralgias other than the trigeminal type, unless it be that of the glossopharyngeal type. Nevertheless, it is likely that the relief obtained is due to the central depressant actions of the drug, the inhalation of the prescribed amount of which may produce stage I anesthesia (Rubinstein and coworkers, 1939). Giddiness, sleepiness and even transient unconsciousness have been observed. Lassitude, nausea, and palpitation are also occasionally noted. The permanency of relief obtained by some individuals without continued use of the drug is unexplained. The disease, however, is likely to exhibit spontaneous remissions. Although, as a rule, no serious consequences occur from the inhalation of trichloroethylene, there is danger of overdosage from self-medication. Eichert (1936) reports two cases which developed *toxic psychoses,* with temporary but alarming symptoms.

Trichloroethylene has been used for the relief of pain in *angina pectoris.* Love (1937) reports that the inhalation of one cc, three or four times a day, may prove moderately helpful in some patients, and believes that the central sedative and hypalgesic action is the basis for this. Krantz and coworkers (1935) have investigated the pharmacological actions of the drug on blood vessels. It would seem doubtful that any direct action on the coronary circulation can account for the relief of anginal pain which may sometimes occur. Rubinstein (1937) obtained relief of *migraine* from inhalation of trichloroethylene in all of his small series of six patients. Less success was observed in this respect by Geiger and Goodman (1937) who found that only about 20 per cent of patients with headache, whether migrainous or otherwise, obtain definite relief from trichloroethylene, but this was sometimes dramatic. It is believed that the central depressant action operates here as it does in the relief of trigeminal neuralgia.

The *toxicology* of trichloroethylene as used in *industry* has been reviewed by Hamilton (1934). She records a series of 284 cases in which 26 deaths occurred. The therapeutic use of the drug carries with it no such danger and it is likely that industrial poisoning may be complicated by the presence of toxic impurities. Damage to the liver is not observed when trichloroethylene is used industrially or clinically, and the drug is less dangerous than chloroform. Despite the fact that no serious untoward effects have been reported from the proper use of this chemical in the relief of certain forms of pain, it should be employed cautiously by patients with the knowledge and supervision of the physician.

CHAPTER 6

GENERAL ANESTHETICS

II. NITROUS OXIDE, ETHYLENE, CYCLOPROPANE, ACETYLENE

NITROUS OXIDE

History. Nitrous oxide (nitrogen monoxide, protoxide, "laughing gas") is the oldest of the inhalation anesthetics, and was prepared by Priestley in 1776. In 1799, Sir Humphry Davy, after experiments on himself, announced that nitrous oxide had anesthetic properties and suggested that it be used to allay physical pain in surgical operations. He wrote as follows, "As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." Davy's suggestion passed unheeded, however, until many years later. It is said that a surgeon named Elsworth, in January 1843, amputated a leg under nitrous oxide anesthesia. The manner in which Wells, in 1844, became interested in nitrous oxide through Colton's demonstration has been described. In 1868, Andrews in Chicago introduced oxygen administration with nitrous oxide, the manner of its use today, and in 1880 Bert introduced the use of nitrous oxide-oxygen mixtures under pressure. As a result of Bert's investigations, the first accurate knowledge of the action of nitrous oxide became known.

Chemistry, Preparations and Properties. Nitrous oxide, N_2O, while not an organic compound, has the typical action of the methane anesthetic series. It is the only inorganic gas which is serviceable as an anesthetic agent. There are several oxides of nitrogen, some being quite toxic, especially the higher oxides such as nitric oxide which may be present in nitrous oxide as an impurity. *Nitrous Oxide* (*Nitrogen Monoxide,* U.S.P., B.P.), is a colorless gas which has a slight but characteristic odor and somewhat sweetish taste. It is marketed in steel cylinders as a colorless liquid under a pressure of 30 atmospheres. As the pressure is released, nitrous oxide returns to the gaseous state. It is readily soluble in water and is heavier than air.

Nitrous oxide is very soluble in blood which takes up 45 volumes per cent, if exposed for a sufficiently long period to high concentrations of the gas. Nitrous oxide does not combine with hemoglobin, and is carried in the blood in solution only. It is excreted unchanged through the lungs but a small fraction, due to the rapid diffusion of the gas, escapes through the skin. The chemical affinities of the gas are feeble and this fact probably accounts for the freedom from side-actions in its use.

The oxygen in nitrous oxide is unavailable for animal respiration, because nitrous oxide does not decompose in the body. Seeds cannot germinate or plants grow in nitrous oxide. A glowing splinter, however, bursts into flame if thrust into the gas, exactly as if thrust into oxygen. On the other hand, the sulfur flame which burns with little heat is extinguished. Thus, only at high temperatures is oxygen dissociated from nitrous oxide. Although nitrous oxide is not inflammable, it supports combustion as actively as does oxygen when it is present in proper concentration with an inflammable anesthetic. Fatal explosions have occurred with ether-nitrous oxide mixtures. Nitrous oxide also enhances the explosiveness of ethylene, and the induction of ethylene anesthesia with this gas entails a definite element of danger. The violence of an ethylene-nitrous oxide explosion is greater than that of ethylene mixed with either oxygen or air. If the two gases are used together, the tanks should not be opened at the same time. In the presence of oil, mixtures of oxygen and nitrous oxide at high pressures are also explosive.

Anesthetic Action

Inhalation of Undiluted Nitrous Oxide. The inhalation of undiluted nitrous oxide produces rapid but light anesthesia. So rapid is the induction that the stages of anesthesia are difficult to follow. When the full effect of the gas is manifested, the patient is barely in plane i of stage III. Nitrous oxide alone, therefore, is not a powerful anesthetic. Undiluted nitrous oxide is employed for very short operations, as in dentistry, and is administered by the use of a tight-fitting mask to exclude air. Dental anesthesia with nitrous oxide is preferably performed with five per cent to 10 per cent oxygen mixtures. No special preparation is needed for these short procedures except a preliminary fast of several hours. The patient may sit in a chair and his clothing need not be removed.

The course of anesthesia with undiluted nitrous oxide is as follows:

Preliminary Effects. The patient notes a sweetish taste. There is no sense of suffocation, despite the absence of air, because nitrous oxide is nonirritating and induction of anesthesia is rapid. Numbness and a sense of comfortable warmth are experienced and noises or rushing sounds are heard in the ears. Confusion rapidly intervenes, and occasionally the patient exhibits exhilaration or bursts into laughter. The respiration becomes deeper and fuller, and the pulse is bounding. Consciousness is lost within 20 to 30 seconds.

Second Stage Anesthesia. The patient may experience extremely vivid dreams, amounting in fact to hallucinations. Many women, for example, have claimed that they were sexually assaulted by the dentist while under nitrous oxide, and insist upon this despite the fact that their husbands may have been with them throughout the operation. Several famous medicolegal cases are based on the property of nitrous oxide to produce hallucinations. The doctor or dentist, therefore, should always have an assistant, preferably a female nurse, when using the gas on women. The course of anesthesia is too rapid to allow for much excitement or struggle. The respirations are deep and rapid, the pulse is accelerated and the blood pressure elevated. The pupils are dilated, and the skin is dusky or cyanotic. Salivation and bronchial secretions are not stimulated. This stage lasts from one-half minute to one and one-half minutes.

Surgical Anesthesia. From one to two minutes after the anesthetic is started, plane i of stage III is entered. The limbs are flaccid, the pupils are still dilated, and the face is cyanotic. Respirations are slightly irregular and stertorous due to relaxation of the soft palate. The blood pressure may rise markedly because of increasing asphyxia. This rise may be due in part to the operative procedure because it is often absent in normal subjects not undergoing surgery. Wright and Thompson (1930) studied the blood pressure responses of healthy persons during the inhalation of pure nitrous oxide and found that after a preliminary rise (psychic) there usually occurred a gradual or sharp decline in blood pressure due to the depressant effect of anoxia on the ventricular myocardium. Electrocardiographic changes occur, chiefly in the T wave in lead two, and are similar to those seen in anoxia, namely, reduction, inversion or abolition of the T wave (Ward and Wright, 1929). The medullary centers are not depressed because of the innocuousness of nitrous oxide. The accompanying anoxia actually stimulates the respiratory and vasomotor centers. Nitrous oxide and ethylene, in fact, are respiratory stimulants throughout anesthesia, and never produce depression by their own action.

When the respirations become stertorous or noisy and the face cyanotic, the gas is discontinued and the mask removed. The operation is now performed. Anesthesia lasts for about thirty seconds to one minute after the mask is lifted, and the operative period is thus very short. The patient is fully awake after one to three minutes. The time from start to finish is only three to five minutes. Anesthesia can be continued longer if some air is let into the mask periodically to overcome the asphyxia, but this is likely to result in an irregular and difficult anesthesia.

Asphyxial Stage. If the administration of undiluted nitrous oxide is continued beyond the stage of anesthesia just described, asphyxial signs rapidly appear. Intense blue-black cyanosis is present, the blood pressure may be markedly elevated, due to the asphyxia, and the pulse is slow. The corneal reflex is absent and muscle twitchings appear and proceed to tonic muscular spasms. Respirations, which are violent as severe asphyxia develops, soon become shallow and irregular, and in two to four minutes cease entirely. The heart continues to beat for some time and therefore restorative measures are fairly easy. The respiratory and circulatory changes are almost entirely secondary to asphyxia.

It should be emphasized that *cyanosis is never an accurate guide to the degree of anoxemia.* A cyanotic color depends on the amount of reduced hemoglobin in the blood, and a patient with severe anemia may be in fatal oxygen lack and yet not have the five grams per cent of reduced hemoglobin necessary for the exhibition of cyanosis. An individual with a hemoglobin value of less than 40 per cent cannot be depended upon to develop cyanosis. The moderately anemic patient with a hemoglobin value of 60 per cent may show cyanosis late in the course of anoxemia, when half of the hemoglobin has already been reduced. Conversely, the polycythemic person may normally be somewhat blue, or become blue very early in the course of nitrous oxide anesthesia when there is still an adequate amount of oxyhemoglobin in the blood. In addition, factors such as the thickness and color of the skin, the density of its capillary network, and the type of lighting used in the operating room all modify the appearance of cyanosis and hence reduce the value of this physical sign. In colored patients, it is difficult to detect cyanosis.

The *muscle twitchings,* especially of the limbs, seen in the asphyxial stage of anesthesia with nitrous oxide, are known as *jactitations.* Convulsions, so prominent in other forms of asphyxia, either do not occur under nitrous oxide or are mild because of the depressant action of the anesthetic on the motor cortex.

Recovery. Recovery is rapid, uneventful and generally without after-effects. Occasionally, slight headache or dizziness may be noted. Hyperglycemia and acidosis, if they develop, are due to anoxia. So rapidly is the gas eliminated from the body that it is no longer detectable in the blood five minutes after anesthesia has been terminated. Nitrous oxide is excreted unchanged, chiefly through the lungs. A small fraction is lost through the skin (Orcutt and Waters, 1933).

Contraindications. The contraindications to the use of undiluted nitrous oxide are in reality those to anoxia. The administration either of undiluted or high concentrations of nitrous oxide is contraindicated in a patient to whom asphyxia, even for relatively brief periods, would be harmful. This especially includes patients with cardiovascular disease, elderly persons, and hypertensive and hyperthyroid individuals. It is often impossible to anesthetize hysterical or highly excited patients with nitrous oxide, and addicts to alcohol may also offer difficulty. Very young children and persons with high metabolic rates are especially intolerant of oxygen deficiency and often cannot be anesthetized satisfactorily with nitrous oxide. For these reasons, even for very short periods of anesthesia, undiluted nitrous oxide is greatly inferior to a mixture of the gas and oxygen.

Inhalation of Mixtures of Nitrous Oxide and Oxygen. In order to allow longer periods of anesthesia than the two-minute limit imposed by asphyxia when undiluted nitrous oxide is used, air or oxygen must be combined with the gas. When a 90:10 mixture (90 volume per cent of nitrous oxide and 10 volumes per cent of oxygen) is inhaled, it is just possible to bring most patients into the first plane of stage III anesthesia (Figure 4), but early signs of anoxia may develop if inhalation of the mixture is continued for any length of time. When nitrous oxide is mixed with 20 volumes per cent oxygen, asphyxial signs are entirely missing. Anesthesia may now be continued, usually for long periods, although the reduced concentration of nitrous oxide weakens the anesthetic action. For example, most patients without preanesthetic medication do not enter the second stage of anesthesia from inhaling an 80:20 nitrous oxide-oxygen mixture. Exhilaration, laughter, staggering gait, slight drowsiness, moderate analgesia, and relatively normal touch sense are observed. Mental confusion occurs but loss of consciousness rarely results. When a sufficient amount of morphine and scopolamine or basal anesthesia with tribromethanol or barbiturate is given beforehand, an 80:20 mixture is quite capable of producing surgical anesthesia.

Under certain circumstances, adequate muscular relaxation can be obtained with nitrous oxide-oxygen mixtures by utilizing the technic described by McKesson (1920). Several minutes after anesthesia has been induced with nitrous oxide and oxygen, pure nitrous oxide is administered until the patient develops dilated pupils, muscular rigidity or spasm, and slow respiration. A single breath of pure oxygen is then allowed and anesthesia is continued with the original nitrous oxide-oxygen mixture. Complete muscular relaxation is obtained by this method and may last for the duration of the surgical procedure. The explanation of the phenomenon is not clear but its efficacy is well established. The patient must be healthy enough to withstand a short period of acute anoxia and the anesthetist should be an expert; otherwise, this procedure is not justified or safe.

Concentrations of nitrous oxide below 80 volumes per cent are capable of producing *analgesia*. The optimal concentration of the gas which allows analgesia without loss of consciousness or cooperation is from 35 to 40 volumes per cent (Seevers and associates, 1937).

The *physical signs* during surgical anesthesia with mixtures of nitrous oxide and oxygen naturally vary with the percentage of each gas and the character of the preanesthetic medication. For example, with a 90:10 mixture and preliminary morphine and atropine, the stage of surgical anesthesia is characterized by regular and stertorous respirations, a slightly dusky skin color without real cyanosis, a moderately elevated pulse rate and blood pressure, and moderately decreased tone. With a mixture of 80 volumes per cent nitrous oxide and 20 volumes per cent oxygen, the respiration, circulation and other vital processes are only slightly affected. Breathing may be slower and deeper without change in respiratory minute volume and the only detectable circulatory change is moderate dilatation of the peripheral capillaries.

Technic of Administration of Nitrous Oxide-oxygen Mixtures. Morphine combined with scopolamine or atropine is administered before nitrous oxide-oxygen anesthesia and greatly enhances the depth to which anesthesia may be carried (Figure 4). Preanesthetic sedation also allows more oxygen to be used in the gas mixture. Basal anesthesia with tribromethanol is frequently employed and nitrous oxide-oxygen is then given as the supplemental anesthetic.

A special gas apparatus and tight fitting mask are required. Anesthesia is induced with a 98:2 nitrous oxide-oxygen mixture, and as the patient enters plane i of stage III, the ratio is gradually changed to 90:10 or 85:15. The ratio of the gases can then be altered to meet the needs of the operation. If muscular relaxation is not complete, supplemental ether or cyclopropane may be administered. Muscle spasms due to insufficient oxygen should not be mistaken for emergence excitement or the anesthetist may erroneously give more nitrous oxide and increase the anoxemia. A difference of two or three per cent in the concentration of nitrous oxide often determines the success of the anesthesia.

Mechanism of Anesthetic Action. Nitrous oxide does not combine chemically with any constituent of the body, and tissues other than the central nervous system are quite unaffected by its presence. The question naturally arises as to whether nitrous oxide is purely an indifferent asphyxiant gas, like nitrogen or hydrogen, or whether it produces anesthesia by direct action on nerve cells. The former view prevailed for some time but it is now definitely known that nitrous oxide is an anesthetic and not an asphyxiant. Although the phenomena seen in anesthesia with pure undiluted nitrous oxide are partly asphyxial in origin, the evidence that nitrous oxide is an anesthetic is incontrovertible.

When nitrous oxide is administered with sufficient oxygen to prevent asphyxia, as in an 80:20 mixture, anesthesia may result in some patients. Indeed, consciousness may be lost with lower concentrations of nitrous oxide, and subanesthetic doses are definitely analgesic. This must be due to the action of the gas on the central nervous system; otherwise an 80:20 mixture would act as air does. For example, if nitrogen is substituted for the nitrous oxide in such a mixture, anesthesia ceases at once. Even if the oxygen content is reduced so that the mixture contains 90 volumes per cent of nitrogen and 10 volumes per cent of oxygen, no anesthesia occurs, whereas it is possible with most subjects to enter the first plane of anesthesia with a nitrous oxide-oxygen mixture of 90:10. Furthermore, respiratory arrest occurs earlier when undiluted nitrous oxide is breathed than when nitrogen is inhaled. Clearly, nitrous oxide is not acting solely through an asphyxial mechanism. Finally, frogs placed in pure nitrous oxide lose their reflexes in five and one-half minutes, but in pure hydrogen the reflexes are preserved for over an hour.

Rôle of the Asphyxial Factor. The asphyxial factor, although secondary, is usually essential for complete surgical anesthesia with nitrous oxide. Bert (1878, 1879) contended from his experiments on animals and patients that nitrous oxide was capable of producing complete anesthesia without asphyxia if given with oxygen under increased pressures. For example, he used an 85:15 mixture of nitrous oxide and oxygen under one and one-quarter atmospheres. This allowed for the administration of nitrous oxide under a pressure equivalent to that obtainable from the pure gas under atmospheric pressure and at the same time assured normal oxygenation of the blood. According to Bert this procedure resulted in adequate surgical anesthesia, and he concluded that if the partial pressure of nitrous oxide was raised to 760 mm of mercury, a sufficient quantity of the gas was dissolved in the blood to assure anesthesia regardless of the oxygen tension.

Brown, Lucas and Henderson (1927) have taken exception to the historical experiments of Bert. Duplicating his conditions on rabbits and cats, they were unable to produce anesthesia. Even when they administered an 80:20 mixture of nitrous oxide and oxygen under increased pressures extending at times to two atmospheres (partial pressure of nitrous oxide about 1200 mm of mercury), complete anesthesia was still not obtainable. The authors draw attention to the fact that criteria for adequate anesthesia are quite different today than they were in Bert's time, and conclude that anesthesia with nitrous oxide is only possible provided there is present a certain degree of anoxia.

It is possible, however, so to increase the partial pressure of nitrous oxide that death results in experimental animals in the absence of anoxia, but three atmospheres or more of pressure are needed (Bock, 1913; Lendle, 1929).

Margin of Safety and Accidents. The margin of safety with nitrous oxide is quite broad, more so than with any other anesthetic. The innocuousness of nitrous oxide in respect to the tissues and vital functions is demonstrated clearly by the fact that dogs, kept continuously anesthetized with nitrous oxide for three days, recovered as readily as if anesthetized for only a few minutes, and without any discernible ill effects. The blood concentrations of nitrous oxide at anesthetic and fatal levels offer no measure of the clinical safety of the gas. For example, the blood concentration of nitrous oxide during complete anesthesia with the undiluted gas is 50 mgm per cent, and at respiratory arrest it is 60 mgm per cent. The apparently narrow margin is due to the fact that the cause of death is asphyxia. If sufficient oxygen is present along with a blood level of 60 mgm per cent, no toxic effects are noted.

The safety of nitrous oxide is best indicated by the rarity of serious accidents and the extremely low mortality figures. With due consideration for the limitations of statistics on anesthetic mortalities, the figure quoted for nitrous oxide of one death in 5,000,000 administrations is probably of the correct order of magnitude. This indicates better results than for any other anesthetic.

Minor accidents due to excitement, temporary asphyxia or hallucinatory dreams may occur. A few cases of sudden respiratory arrest and death in healthy patients without the presence of anoxemia have been reported. There is some evidence that sensitized carotid sinus respiratory reflexes may have been involved.

Advantages and Uses of Nitrous Oxide. Nitrous oxide is non-toxic and the safest of all anesthetics. It is entirely non-irritating and has no untoward side-actions. The gas is not injurious to parenchymatous organs, and causes practically no metabolic disturbances in the body. Indeed, except for the fact that nitrous oxide is a relatively weak central nervous system depressant, it would qualify for the ideal gas anesthetic.

Nitrous oxide has proved of great value in dentistry, especially before the use of local anesthesia became commonplace. Nitrous oxide-oxygen mixtures (80:20) are useful for analgesia in labor, *when given by an expert anesthetist* so that an adequate supply of oxygen is constantly supplied both for the mother and child. The course of labor is not impeded.

A special use of nitrous oxide is for the rapid, pleasant and safe *induction of general anesthesia,* as in "gas-ether" sequence, first suggested in 1876 by Clover. It reduces anxiety and avoids the excitement stage of ether anesthesia. After induction with nitrous oxide, ether is gradually added while the nitrous oxide is withdrawn. The effects of ether and nitrous oxide are purely additive.

Disadvantages. The disadvantages of nitrous oxide are chiefly those of anoxia. Nitrous oxide given undiluted or with very low concentrations of oxygen is not satisfactory for any operation lasting longer than from thirty seconds to one and one-half minutes. When oxygen in sufficient concentration to prevent anoxemia is employed with nitrous oxide, the degree of muscular relaxation required in major surgical procedures is not easily obtained. Without adequate oxygen, the resulting cyanosis, acidosis, rise in blood pressure, tachycardia, etc., make nitrous oxide dangerous in patients with high blood pressure, cardiovascular disease and high metabolic rates. It is often impossible to anesthetize patients with high reflex excitability. Finally, nitrous oxide anesthesia necessitates special apparatus and an experienced anesthetist. It is clear, therefore, that the principal disadvantage of the gas is the fact that, being a weak anesthetic, it has a limited sphere of usefulness unless given with adequate oxygen and supplemented by proper preanesthetic medication, basal anesthesia or other anesthetic agents. The dangers of cerebral damage from anoxia incident to the use of nitrous oxide already have been presented (page 55).

ETHYLENE

Historical. Hermann (1865) was the first to note the anesthetic action of ethylene. Similar work was reported by Eulenberg (1876) and Luessem (1885) but no practical results were forthcoming until Crocker and Knight (1908) noted the toxicity for plants of ethylene in very high dilutions. In that year, certain carnation growers suffered heavy financial loss because the flowers shipped to Chicago "fell asleep" in the greenhouses and the buds failed to open. Crocker and Knight of the Hull Botanical Laboratory studied the illuminating gas used in the greenhouses and found ethylene, which comprised four per cent of the gas, to be the toxic agent. A dilution of 1:2,000,000 of ethylene in air is sufficient to affect carnations. The anesthetic action of ethylene on animals was rediscovered independently by Luckhardt and Lewis (1923) and by Brown (1924). Luckhardt and Lewis were active in the successful development of ethylene as a surgical anesthetic. Clinical surgery under ethylene anesthesia was first performed in 1923.

Chemistry. *Ethylene* (U.S.P., B.P.), $H_2C=CH_2$, is an unsaturated hydrocarbon of the olefin series. It is a highly volatile colorless gas which has a slightly sweet taste and not unpleasant odor. The gas is soluble in water 1:9 by volume, and has a boiling point of −103.9 C. Ethylene is lighter than air whereas ether and cyclopropane are heavier. It is furnished in compressed form in metal cylinders. For use as an anesthetic, ethylene is marketed free from impurities, the presence of which has caused several accidents. Ethylene is explosive and inflammable when present in oxygen mixtures of certain strength, though by itself it is not explosive and will not support combustion. Explosiveness is the greatest drawback to the use of ethylene.

Actions. Ethylene has the typical action of the methane anesthetic series. Ethylene-oxygen mixtures produce satisfactory anesthesia with practically no effect on vital functions. The innocuousness of ethylene for tissues is its outstanding advantage.

Induction. The speed of induction is rapid, exceeding that of nitrous oxide. After the patient has taken six or more deep inhalations, mental clouding supervenes and unconsciousness soon follows. Induction is not disagreeable, although an occasional patient (or surgeon) may complain of the odor of the gas. The purer samples are usually free of objectionable odor. Ethylene does not irritate the respiratory mucosa and hence reflex respiratory irregularities during induction are absent. When the pure gas is inhaled, however, a sense of suffocation is experienced and reflex choking or swallowing may occur. Bronchial secretions and salivation are not stimulated by ethylene.

Anesthesia. Full surgical anesthesia occurs in from two to five minutes. Ethylene is a more powerful anesthetic than nitrous oxide, but less powerful than cyclopropane or ether. Under favorable conditions, it can carry anesthesia to the lower border of plane i, that is, 25 per cent of the way through the third stage (Figure 4). This fact accords ethylene an anesthetic potency of 25 per cent in comparison with nitrous oxide which has a potency rating of 15 per cent (Guedel, 1937). It may be recalled that the agents possessing a 100 per cent potency rating are ether, chloroform, divinyl oxide and cyclopropane (page 50). Subanesthetic concentrations of ethylene, however, are definitely analgesic and the inhalation of 25 to 35 volumes per cent of ethylene produces analgesia without loss of consciousness or cooperativeness (Seevers and associates, 1937). On this basis, ethylene is only one-sixth as potent as cyclopropane, which requires but four to six volumes per cent, and slightly more potent than nitrous oxide, which requires 35 to 40 volumes per cent for analgesia.

The induction of surgical anesthesia requires 90 volumes per cent of ethylene, leaving only 10 volumes per cent of oxygen available. Unless the concentration of ethylene is at least 90 per cent to start with, it may be impossible to induce surgical anesthesia. Once surgical anesthesia is obtained, however, the concentration of ethylene may be reduced to 80 volumes per cent and the concentration of oxygen increased to 20 volumes per cent, without lessening the degree of anesthesia. This allows sufficient oxygen to prevent anoxia and acidosis. Ethylene anesthesia provides an excellent example of the value of preanesthetic medication. When this is adequate, full anesthesia can be induced with an 80:20 mixture. Anesthesia is usually induced, however, with a 90:10 mixture.

Muscular relaxation is more profound with ethylene than with nitrous oxide anesthesia, but much less so than with ether. Even with satisfactory preliminary medication, upper plane ii is rarely exceeded, and ethylene must be supplemented with a small amount of ether when operations requiring complete muscular relaxation are undertaken.

Respirations during surgical anesthesia under ethylene are quite normal, slow and regular. Ethylene is never a respiratory depressant by its own action, and it is thus impossible to produce respiratory paralysis by the action of ethylene alone. The medulla is not depressed; it may even be slightly stimulated by the lowered oxygen tension incident to the use of ethylene in concentrations over 85 volumes per cent. The *blood pressure* may rise moderately during the induction and early phase of surgical anesthesia, probably due to the slight anoxemia, but it soon returns to normal and remains there throughout the operation. The cardiac output may increase under ethylene anesthesia. Arrhythmias occur less frequently when ethylene is used than with any other general anesthetic (Kurtz and coworkers, 1936). The cardiovascular effects of the gas, therefore, are extremely benign. The isolated mammalian heart, for example, is unharmed when perfused with fluid saturated with the gas. Anoxemia during induction is very slight and insufficient to produce cyanosis. The *color* therefore remains good. The fall in body *temperature* is not as marked as with ether; there is no sweating, and salivation is negligible or absent. Pulmonary irritation does not occur and the secretion of *bronchial mucus* is not stimulated. Ethylene is thus often the anesthetic of choice for many types of thoracic operations, especially in patients with pulmonary disease. *Renal and hepatic functions* are unimpaired by the gas and the *metabolic changes* are insignificant when anoxia is avoided. *Acidosis* occurs less often with ethylene than with ether or chloroform. The respiratory mechanism of the fetus is not depressed when ethylene is used in obstetrics, nor is uterine activity impaired.

Recovery. Recovery from anesthesia is quite rapid. As a rule, the patient is awake with a clear mind and able to talk within two or three minutes after cessation of administration of the gas. In fact, so rapid are induction and recovery that the constant attention of the anesthetist is required to maintain even anesthesia in the desired plane. Speedy recovery with quick restitution of the cough reflex is especially important in chest surgery or pulmonary disease. Ethylene is excreted almost quantitatively in the exhaled air and undergoes no chemical changes in the body.

Postanesthetic nausea or vomiting is somewhat less frequent and less severe than after ether, the incidence with ethylene being 33 per cent as compared with 57 per cent for ether (Waters, 1936). Gas pains likewise are milder and less frequent after ethylene, and the incidence of postoperative distention is only seven per cent as compared with 16.5 per cent for ether. The entire intestinal musculature is stimulated rather than depressed with light ethylene anesthesia, and remains normal during deeper planes of anesthesia.

Preanesthetic Medication. Preliminary medication for ethylene anesthesia does not differ from that used for other inhalation anesthetics, and is practically indispensable. By decreasing the amount of ethylene needed, it permits a greater percentage of oxygen in the mixture, and by reducing the patient's reflex irritability, a deeper plane of anesthesia can be reached. Furthermore, smooth induction is facilitated.

Advantages. Ethylene has many advantages as an anesthetic agent. It allows a rapid, pleasant and safe induction. Excitement and struggle are minimal or absent. There is practically no induction asphyxia. Recovery from anesthesia is rapid and postoperative complications are relatively infrequent. Respiratory and vasomotor depression and metabolic disturbances are not encountered. Pulmonary and renal irritation are absent, and salivary and bronchial secretions are not troublesome. Sweating is not produced and thus water loss and fall in body temperature are not pronounced. More complete muscular relaxation is possible with ethylene than with nitrous oxide. The advantages of ethylene have been reviewed by Guthrie and Woodhouse (1940) on the basis of their experience with the gas in over 35,500 anesthesias.

Fatalities. Death from concentrations of ethylene employed in clinical anesthesia is extremely rare. In order to increase the concentration of the gas to the point of toxicity, the oxygen must be so greatly reduced that the resulting symptoms are almost entirely the result of asphyxia. It is difficult to kill animals with ethylene *per se* unless the pressure of the gas is increased. For example, under two atmospheres pressure, 70 volumes per cent of ethylene (partial pressure 1064 mm) are required to kill mice when adequate oxygen is present.

Disadvantages. The chief disadvantage of ethylene is that it is explosive in certain oxygen mixtures. Accidents with fatalities have occurred, especially in the early days of the use of ethylene, and certain hospitals do not permit the use of this gas. However, the present precautions against explosions are quite sufficient, and include the strict avoidance of flames and sparks, the use of the cautery only under definite restrictions, and the humidification of the atmosphere to at least 60 per cent saturation. Ethylene-nitrous oxide mixtures are violently explosive, and if the gases are used together the two cylinders should never be opened at the same time. The explosive range of ethylene-oxygen mixtures is broad, the most dangerous mixture being from five to 25 per cent ethylene diluted with air or oxygen. Therefore, the most critical time is at the end of anesthesia when ethylene is discontinued. The exhaled mixture remains in the explosive range for three to four minutes after ethylene is stopped. The usual anesthetic concentration for induction, 90:10, is beyond the explosive limits because ethylene-oxygen mixtures do not ignite if the ethylene concentration is above 80 or below 2.5 per cent. Nevertheless, the anesthesia should be conducted at all times as if an explosive mixture were being handled.

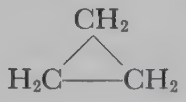
Ethylene provides less muscular relaxation than is obtainable with ether. This is not a serious disadvantage, however, for with proper preliminary medication or slight amounts of supplemental ether, deeper planes of surgical anesthesia are possible. A special gas apparatus is needed for ethylene anesthesia, as is also an anesthetist who has had considerable experience with the gas.

Special Uses. In addition to the usefulness of ethylene anesthesia for general surgical procedures, it may be of special value in obstetrics. *Obstetrical analgesia,* sufficient in degree until the presenting part distends the vulva, is possible with only 25 to 50 per cent ethylene in air. Ethylene does not inhibit uterine activity during labor (Rucker, 1926). The incidence of fetal asphyxia is only one-half that experienced with nitrous oxide-oxygen obstetrical analgesia. Some believe, however, that ethylene increases post partum bleeding. The intermittent administration of ethylene in labor to control pain entails a serious danger of explosion. The entire explosive range of the gas is passed through during each induction or emergence from ethylene analgesia and the frequent application and removal of the mask invites the production of a static spark between the mask and the patient's face. Several fatal explosions have occurred in this manner. Ethylene has been employed in *encephalography,* the gas being injected in the subarachnoid space in place of air.

CYCLOPROPANE

Historical. Cyclopropane was first prepared and described as trimethylene in 1882 by von Freund, but its anesthetic properties were not appreciated. Years later, propylene ($CH_3 \cdot CH:CH_2$), an isomer of cyclopropane, was studied extensively for its usefulness as a general anesthetic but it was found to be too toxic for the heart. In searching for the cause of this toxicity, Lucas and Henderson (1929, 1930) tested cyclopropane as a possible impurity. Cyclopropane was not only exonerated from being the cause of the toxicity of propylene but was found in itself to be a safe and potent anesthetic agent. The first clinical reports came from the Department of Anesthesia at the University of Wisconsin General Hospital after a three year period of study and clinical trial (Waters and Schmidt, 1934).

Chemistry and Preparations. *Cyclopropane,* U.S.P. XI (1939 Supplement), is the simplest possible cyclic hydrocarbon, with the following structural formula:



Cyclopropane

Cyclopropane is a colorless gas with a mildly pungent but not unpleasant odor and taste. In anesthetic concentrations, it is odorless. It is stored in metal cylinders as a liquid under pressure, and remains quite stable. Cyclopropane is heavier than air, and is inflammable and explosive. The explosive range of cyclopropane in air is 3.0 to 8.5 per cent; in oxygen, 2.5 to 50 per cent.

Effective Anesthetic Concentrations. Cyclopropane is the most potent of the anesthetic gases. It can cause analgesia without unconsciousness if continuously inhaled in a concentration as low as three to five volumes per cent (Seevers and associates, 1937). The average concentration of cyclopropane in the respiratory tract as determined by gas analyses during various planes of surgical anesthesia in man is as follows (Waters and Schmidt, 1934): plane i, 7.4 per cent; plane ii, 13.1 per cent; plane iii, 23.3 per cent; plane iv, 42.9 per cent. These anesthetic concentrations apply when preliminary medication with morphine has been given. Without preliminary morphine, for example, 26 volumes per cent of cyclopropane are needed to produce plane ii. These data provide another example of the value of preanesthetic medication.

Two important clinical advantages are immediately apparent. A wide margin of safety exists between the anesthetic and toxic concentrations of the gas (13 per cent vs. 43 per cent). The concentration of cyclopropane required for anesthesia is so low that the oxygen content of the anesthetic mixture can always be 20 per cent or more. Even with air as a vehicle, adequate oxygenation of the tissues is possible; but oxygen is ordinarily used as the diluent.

Anesthetic Actions. *Induction.* Induction with cyclopropane is pleasant, more rapid than with ether, but less so than with nitrous oxide or ethylene. Unpleasant subjective sensations are eliminated by the use of sufficient oxygen and the "head fullness" noted with nitrous oxide is absent. Cyclopropane is not irritating to the respiratory tract and therefore respiratory irregularities do not occur. Salivation is not prominent. Laryngospasm develops only with higher concentrations than are ordinarily required. Although cyclopropane is a gas like nitrous oxide and ethylene, it has the anesthetic potency of chloroform, and the anesthetist must therefore be on guard not to rush the patient from one stage to another.

Unconsciousness occurs in from 20 seconds to three minutes. In about five minutes plane ii of stage III is reached. Cyclopropane does not cause dreams as does nitrous oxide or ethylene.

Physical Signs. Physical signs during cyclopropane anesthesia are similar to those with other anesthetics, except for the following features concerning respiration. (1) The patient can breathe an anesthetic concentration of cyclopropane without respiratory irritation or laryngospasm, as the gas is without irritating properties. This means that the normal physiological protections (coughing, apnea, laryngospasm, struggle) against a sudden increase in concentration are absent. (2) Cyclopropane is not a respiratory stimulant and does not cause an initial increase in the rate and minute volume of respiration as do ether, nitrous oxide and ethylene. Therefore no change in respiration is noted with cyclopropane until the onset of respiratory depression (Figure 8). (3) Diaphragmatic breathing in plane iii is not exaggerated nor is the respiratory rate elevated with cyclopropane as with other anesthetics. Therefore one must watch closely the rebreathing bag in this plane for the first evidence of impending apnea of plane iv.

Danger Signals. Not only does the respiration fail to provide useful physical signs incident to deep anesthesia, but certain less important danger signals are obscured by cyclopropane anesthesia. These are the pupillary changes and the color of the skin.

The value of the *pupils* in judging the depth of anesthesia is diminished by the preliminary administration of morphine and atropine. Despite the action of these alkaloids, with most anesthetics the pupils usually dilate as anoxia develops in lower plane iii. When preanesthetic medication is used with cyclopropane, however, only slight and late pupillary dilatation occurs. Even the fourth stage of anesthesia is often entered without pupillary changes, and dilatation is not marked until the reserve oxygen of the tissues is depleted after respiratory arrest. Without preliminary medication, pupillary dilatation may occur with cyclopropane in the lower third or upper fourth plane.

The *color of the skin* cannot be used as an index of danger during cyclopropane anesthesia because oxygen is given in sufficient excess so that the skin is pink at all times.

The *pulse changes* are the best warning indices with cyclopropane. Arrhythmias, slowing of the heart to 50 beats or less per minute, or definite tachycardia should warn the anesthetist to decrease the concentration of cyclopropane.

Respiration. Certain aspects of respiration have already been discussed. Breathing is very quiet throughout anesthesia. No depressant effect is seen even with deep surgical anesthesia (Figure 8). When apnea occurs in plane iv, a reduction in cyclopropane is sufficient to restore breathing. The high oxygen tension and quiet respiration characterizing cyclopropane anesthesia may make massive atelectasis difficult to detect, and deaths have occurred from this complication (Jones and Burford, 1938). Indeed, cyclopropane-oxygen anesthesia may possibly contribute to the atelectasis by the loss of non-absorbable sustaining nitrogen from the lungs (page 53). Atelectasis may then result from the complete absorption of cyclopropane and oxygen from the distal alveoli during the deeper levels of anesthesia, when the respiratory volume is decreased, and after the sudden withdrawal of the anesthetic mixture at the termination of anesthesia. It has therefore been suggested (Burford, 1938) that some slowly absorbed inert gas such as helium be used in the anesthetic mixture in order to prevent alveolar collapse.

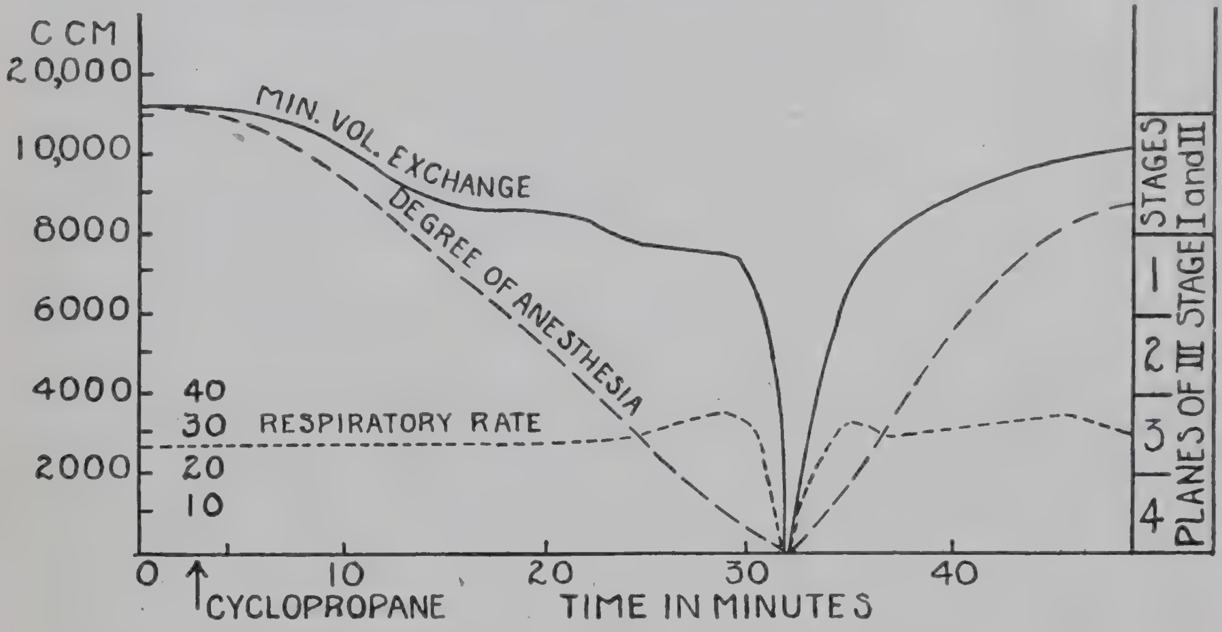


Figure 8. *The effect of cyclopropane anesthesia on respiration in man.*

Tidal exchange and respiratory rate were measured by means of a water spirometer arranged in the closed circuit to record on a kymograph. Minute volume exchange was calculated from these data. Anesthesia was purposely induced gradually and the various stages and planes were passed through slowly so that the point of respiratory arrest was reached in 28 minutes. Cyclopropane was then stopped and pure oxygen administered, and respiration was resumed spontaneously within 30 seconds.

Observe that no increase in rate or tidal volume of respiration occurred after cyclopropane anesthesia was started. Rather, a very gradual decrease in depth but not in rate occurred until intercostal paralysis of plane iv was reached, at which point an increase in rate began which was insufficient to maintain efficient respiratory exchange. Thus, cyclopropane causes no stimulation of breathing during induction, and only slight depression as anesthesia advances, until a concentration is reached which shortly will result in respiratory arrest. (After Waters, 1936. Courtesy of the *British Medical Journal.*)

The absence of respiratory depression during cyclopropane anesthesia is a distinct advantage to the mother and child in obstetrical procedures. In this connection, Rosenfeld and Snyder (1939) studied the respiratory depressant effects on rabbits at term of a number of agents (pentobarbital, morphine, paraldehyde, chloral hydrate, ether, nitrous oxide and cyclopropane). Only cyclopropane produced full surgical anesthesia in the mother without depressing or abolishing fetal respiration.

Cardiovascular System. Anesthetic concentrations of cyclopropane have little effect on the *blood pressure.* The rises which occur are probably related to carbon dioxide retention, anoxia or pressor reflexes, and are not seen if these factors are avoided (Seevers and Waters, 1938). Cyclopropane tends to dilate peripheral vessels and capillary oozing may be increased. The cardiac rate is usually slowed somewhat during stage III.

Arrhythmias of various types have been reported. Kurtz and coworkers (1936) recorded electrocardiographically the occurrence of ventricular extrasystoles in 56 per cent of a series of 41 patients given cyclopropane anesthesia (Figure 9) but approximately half of the patients had heart disease. Waters (1936) has reported from analysis of a large series of anesthetic administrations that cyclopropane causes a higher incidence of arrhythmia (detectable by palpation of the pulse) than does ether. The relative incidence in different planes of anesthesia is shown in Table 2, a study of which indicates that cyclopropane differs from ether (and chloroform) in that cardiac arrhythmias are more apt to occur as the depth of cyclopropane anesthesia increases. This agrees with the observations of Meek and collaborators (1937) who found that epinephrine caused tachycardia of ventricular origin in the dog more readily under deep than under light cyclopropane anesthesia.

TABLE 2

INCIDENCE OF ARRHYTHMIAS *

(Waters, 1936.)

	CYCLOPROPANE			ETHER		
Stage III	Cases	Number	%	Cases	Number	%
Plane i	635	13	2.22	31	2	6.45
Plane ii	1263	72	5.70	275	7	2.54
Plane iii	471	37	7.86	305	8	2.62
Plane iv	298	38	12.72	115	2	1.74
Total	2667			726		

* As detected by palpation of the pulse.

Probably the most common form of arrhythmia seen under cyclopropane is *ventricular tachycardia.* For this reason, premature operative stimuli and epinephrine should be strictly avoided because of the possible danger of causing ventricular fibrillation. Indeed, Meek and associates (1937) found that tachycardia of ventricular origin in the dog was more readily induced by an injection of epinephrine during cyclopropane than during ether or chloroform anesthesia. Also, Orth and coworkers (1939) demonstrated that epinephrine and a number of related sympathomimetic amines so sensitize the ventricular automatic tissue of dogs that cyclopropane anesthesia then causes multifocal ventricular tachycardia. It is generally agreed that clinical arrhythmias are especially likely to occur with an excessive concentration of cyclopropane or when anoxia is present. Kurtz and coworkers (1936) purposely carried cyclopropane anesthesia to plane iv in 41 patients and noted four instances of "multiple focus ventricular tachycardia." This type of disorder is similar to that noted by Hill (1932) during chloroform anesthesia in man (page 62), and by Levy (1914) preceding ventricular fibrillation due to chloroform anesthesia in cats. Waters (1936) records that two of three deaths occurring during 7200 administrations of cyclopropane were probably due to ventricular fibrillation.

Although arrhythmias, including ventricular tachycardia, extrasystoles and A-V blocks, have been produced experimentally in animals under cyclopropane anesthesia, there is no clinical or laboratory evidence to indicate that the disturb-

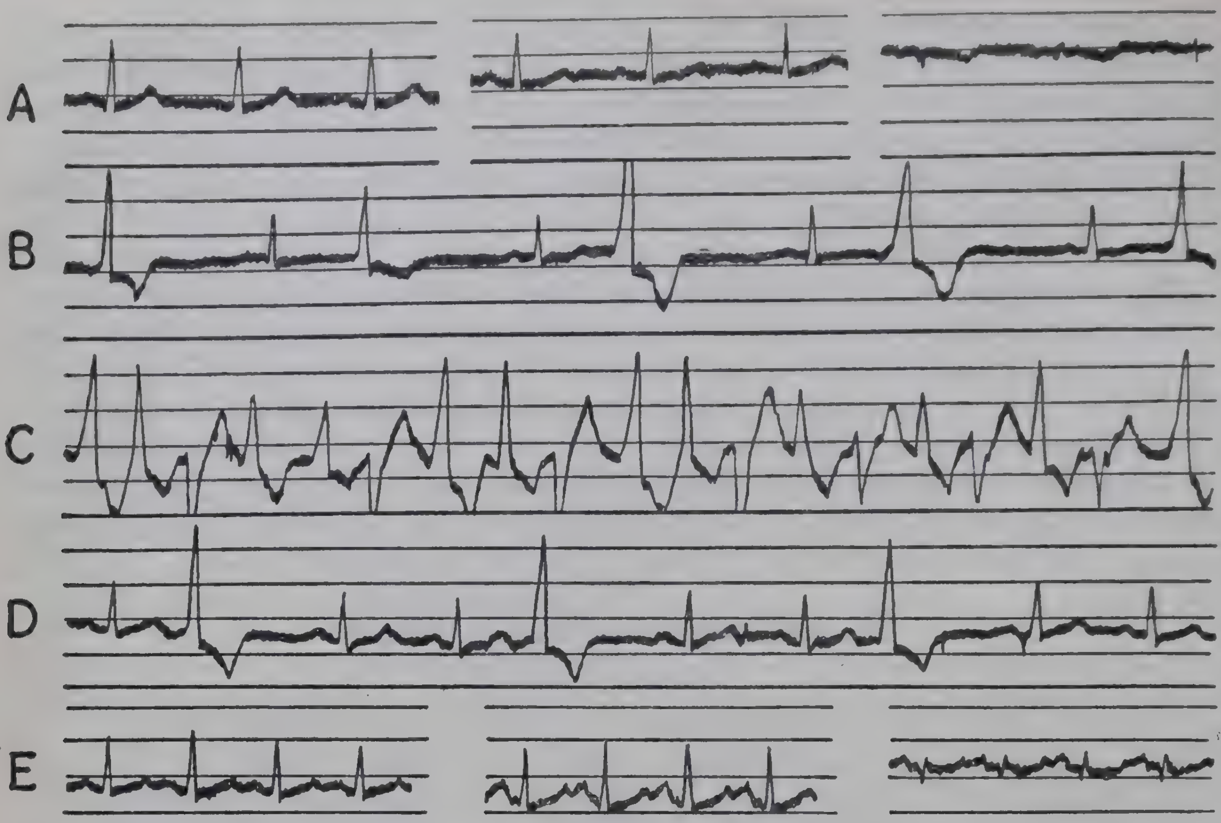

FIGURE 9. *Electrocardiographic abnormalities caused by cyclopropane anesthesia.*

Woman, aged 32, with a normal heart; pelvic operation. *A.* Before operation: normal tracing in leads I, II and III. *B.* First plane anesthesia, 10 minutes after induction and during preparation of operative field: lead II shows ventricular extrasystolic rhythm. *C.* First plane anesthesia, 36 minutes after induction, during exploration of abdomen: lead II shows multiple focus ventricular tachycardia. *D.* First plane anesthesia, 43 minutes after induction: ventricular extrasystoles. *E.* Ten hours after operation: normal sinus rhythm restored. (After Kurtz, Bennett and Shapiro, 1936. Courtesy of *The Journal of the American Medical Association.*)

ance is other than functional and transitory. Myocardial injury could not be detected in dogs by anesthetic concentrations of the gas sufficient to cause respiratory arrest (Meek and Volpitto, 1936), and the cardiac output is considerably increased under moderate cyclopropane anesthesia (Robbins and Baxter, 1938).

It has been suggested by Robbins and his associates (*see* Robbins, 1940) that the character of the preanesthetic medication employed prior to cyclopropane anesthesia may be an important factor in determining the occurrence of cardiac irregularities. For example, in dogs without preanesthetic medication and under artificial respiration, the cyclopropane concentration of the blood can be increased approximately 30 per cent over that required for respiratory arrest without the occurrence of electrocardiographic changes. After preanesthetic medication with morphine, the same types of electrocardiographic abnormalities occur in dogs during cyclopropane anesthesia as those most frequently observed clinically. However, when barbiturates are administered prior to cyclopropane, cardiac arrhythmias do not occur until long after respiratory arrest. Inasmuch as morphine is frequently administered before cyclopropane anesthesia in human beings, it is important to determine whether this alkaloid is a factor in the arrhythmias described.

In *summary,* it may be stated that clinical experience has shown cyclopropane, administered expertly, to be a safe agent as regards the cardiovascular system, even in cases of bad risks and cardiovascular disease. Experimentally, however, there is evidence to indicate the occurrence of sensitization of the automatic tissue of the heart and arrhythmias of a transitory and purely functional nature. Although disturbances of rhythm during both general and local anesthesia occur far more often than is generally recognized (only 21 per cent of 109 cases of anesthesia by various agents studied by Kurtz and associates [1936] failed to show irregularities), nevertheless the cardiac effects of cyclopropane deserve further study. The actions of cyclopropane anesthesia on the circulatory system have been extensively reviewed by Robbins (1940).

Muscular Relaxation. As a rule, muscular relaxation is quite sufficient for most operations; indeed, cyclopropane has been used in every type of surgical procedure, including obstetrical surgery. In some difficult abdominal operations, a small amount of supplemental ether may be necessary.

Metabolic Effects. Extensive studies of the blood and urine, and of functions of the kidneys and liver show no deleterious effects of cyclopropane. The functional capacity of the liver is not depressed (Raginsky and Bourne, 1934). No significant changes are noted in the blood levels of non-protein nitrogen or sugar or in CO_2-combining power during or after clinical anesthesia with cyclopropane, either in the normal or diabetic patient (Waters and Schmidt, 1934; Neff and Stiles, 1936; Robbins, 1940).

Recovery. Recovery from cyclopropane anesthesia occurs with the same speed as from nitrous oxide and ethylene, that is, within a few minutes after cessation of anesthesia. Nausea and vomiting are less severe and less frequent than after ether but more common than after nitrous oxide and ethylene. The same is true of postoperative distention (Waters, 1936). Pneumonia and atelectasis are much less common than after ether. Schmidt and Waters (1935) noted fewer respiratory complications in over 2000 patients anesthetized with cyclopropane than in an equal number of cases anesthetized with other anesthetics. Tachycardia and severe postoperative fall in blood pressure are perhaps more frequent with cyclopropane than with ether, but the absolute incidence is low. Headache apparently occurs more commonly during recovery from cyclopropane than from other general anesthetics.

Technic of Administration. A closed circuit method is used for cyclopropane, and a modernly constructed or adapted gas-oxygen machine is required. The patient rebreathes an oxygen-cyclopropane mixture, and the exhaled carbon dioxide is absorbed. A constant metered flow of oxygen replaces the oxygen consumed and more cyclopropane is added to the mixture as it is needed. When the desired plane of anesthesia is reached and muscular relaxation is adequate, the flow of cyclopropane is discontinued and the patient rebreathes the existing mixture. Often a pharyngeal airway is used with cyclopropane; some anesthetists prefer the use of an endotracheal airway fitted with an inflatable tracheal cuff, thus dispensing with the face mask. The cost of cyclopropane for the average operation is about 50 cents per hour, during which time one gallon of the gas is used.

Preanesthetic Medication. Atropine or scopolamine is essential before cyclopropane anesthesia in order to reduce the slight amount of mucus secretion which otherwise would occur. Some anesthetists prefer to use avertin for basal anesthesia and cyclopropane as the supplemental agent. In fact, Wood (1936) believes this type of combined anesthesia approaches the "mythical ideal" and that the surgical mortality and morbidity are lower than with any other anesthetic agent. Accurate timing of preanesthetic medication is essential to this technic. Not over 10 mgm of morphine are given with 0.4 mgm atropine one hour before avertin. Avertin is then administered in the dose of 60 to 80 mgm per kg, 30 or 40 minutes prior to cyclopropane. Only rarely are small amounts of ether needed for more complete muscular relaxation. When morphine or barbiturate is employed prior to cyclopropane anesthesia, the concentration of gas needed for a given plane of surgical anesthesia is considerably reduced, as aforementioned (*see also* Robbins, Baxter and Fitzhugh, 1939).

Absorption and Excretion. Cyclopropane is rapidly absorbed and eliminated. It is entirely excreted from the body by way of the lungs. At the time of awakening, the concentration of cyclopropane in the expired air has fallen to one per cent and only traces are found at the end of three hours.

Advantages. Cyclopropane allows more than adequate oxygen throughout all depths of anesthesia. It is nonirritating and does not cause respiratory irregularities in stage II. Anesthetic concentrations do not depress the heart or circulation. Salivation is not prominent. Deleterious metabolic effects are singularly absent. Liver injury, as measured by the bromsulfalein dye excretion test, does not occur. Postanesthetic recovery is rapid and smooth, with less nausea and vomiting, less postoperative distention and fewer respiratory complications than after ether. The reports of Taylor and associates (1937) and Burford (1938) indicate that postoperative pulmonary complications occurred in less than one per cent of over 7000 cyclopropane administrations, but the incidence is closer to two per cent when calculated only on the basis of abdominal operations. Cyclopropane produces greater muscular relaxation than does any other anesthetic gas, although third plane anesthesia may be necessary to obtain the desired degree. Finally, there is a wide margin of safety between anesthetic and toxic concentrations, perhaps wider than that existing for any other anesthetic agent now in use.

Disadvantages. Cyclopropane is explosive and inflammable within the entire range of anesthetic mixtures. It is less explosive, however, than ethylene or nitrous oxide-ether mixtures. Great care must be observed if the cautery or electric knife is employed during anesthesia with cyclopropane, and while they are being used, no gas should be released from the breathing bag. Fat burns with a more active flame during cyclopropane anesthesia than during ethylene anesthesia, due to the high percentage of oxygen present. After the administration of cyclopropane is stopped, the exhaled air is still inflammable for from six to eight minutes. Anesthesia with cyclopropane requires a completely closed circuit with a carbon dioxide absorption system, both for safety and economy. The cost of the gas would be prohibitive unless a closed system were used. Cyclopropane must be given by an experienced anesthetist. Some surgeons claim that cyclopropane produces capillary oozing, although others deny this. Lastly, the status of cyclopropane in regard to its effects on the heart has not been finally determined, and the gas should be avoided in patients in whom the use of epinephrine during anesthesia is anticipated.

Indications and Uses. Cyclopropane has been successfully employed in every type of surgical operation. It is especially useful when maintenance of tissue oxygenation is of paramount importance, as in pregnancy and in patients with exophthalmic goiter, congestive heart failure, grave circulatory complications, anemia, and pulmonary disease or respiratory obstruction. Cyclopropane anesthesia is particularly valuable in chest surgery because of the quiet respirations, plenitude of oxygen, absence of laryngospasm and bronchial irritation, and quick recovery of the cough reflex (Eversole and Overholt, 1936; Rovenstine, 1935). In obstetrical procedures, the gas may be employed for analgesia or anesthesia.

The fact that cyclopropane has no depressant action on the respiratory system of the mother and child is a definite advantage, and uterine activity is not depressed (Bourne, 1934).

ACETYLENE

Acetylene is a colorless, highly volatile and explosive gas with a pungent ethereal odor, and possesses the typical action of the methane series of anesthetics. Its formula is $HC \equiv CH$. Commercial acetylene contains impurities which produce toxic effects and even the pure gas must be passed through water or over activated carbon to remove the acetone in which the acetylene is stored in solution. Even when pure, acetylene has a disagreeable odor. Anesthesia in man requires approximately 60 to 80 volumes per cent of the gas, but muscular relaxation is not adequate in the majority of patients and plane iii is not obtainable without anoxia. Although acetylene once enjoyed some use as a surgical anesthetic agent in Europe, it has not been employed to any extent in the United States. It is more explosive and not as satisfactory an anesthetic as ethylene, the gas which it most closely resembles.

Acetylene is not metabolized by the body, and is rapidly absorbed and excreted by the lungs. It has been found serviceable as a gas for the determination of cardiac output (Grollman, 1932).

CHAPTER 7

BASAL ANESTHETICS

TRIBROMETHANOL

(AVERTIN)

Historical. Tribromethylalcohol was introduced in 1926 by Willstaetter and Duisberg as a "fixed-dose" anesthetic for rectal administration. Its main use today is for basal anesthesia, expert anesthetists agreeing that it should not be employed alone for full surgical anesthesia. Avertin has been widely used as a basal anesthetic and sufficient clinical data are available to allow a proper evaluation of its uses and dangers. *Avertin with Amylene Hydrate* (N.N.R.) is the Council-accepted preparation.

Chemistry and Preparations. *Tribromethanol,* CBr_3CH_2OH, is closely related chemically to chloral (CCl_3CHO) and to ethyl alcohol (CH_3CH_2OH), three bromine atoms being substituted in the latter to produce avertin. Bromination of ethyl alcohol greatly increases the anesthetic action of the drug, another example of the increase in anesthetic potency resulting from halogenation of an aliphatic hydrocarbon. The bromide ion as such does not contribute to the depressant action, because tribromethanol does not dissociate in the body to any extent. Traces of bromine, however, may be found in the breath and sweat (Parsons, 1931) after the administration of the drug.

Avertin is a white crystalline powder with a slight aromatic odor and taste. It decomposes slowly at room temperature and rapidly above 40 C. Its aqueous solubility is rather low (1:35) and therefore the drug is marketed as *Avertin with Amylene Hydrate* (N.N.R.) (formerly called Avertin-Liquid), a solution of avertin in a special liquid solvent, *amylene hydrate.* Because the solvent is volatile and avertin decomposes on exposure to light, the solution should be kept in well-stoppered brown bottles. Amylene hydrate is also inflammable.

Amylene Hydrate. Amylene hydrate is a central nervous system depressant, but plays a minor rôle in the anesthesia produced by avertin with amylene hydrate. One cc of this solution contains one gram of avertin and one-half gram of amylene hydrate. In the following discussion, whenever the dose of avertin is given, it refers to avertin with amylene hydrate and therefore one-half of the same weight of amylene hydrate is automatically included. In describing the actions of avertin, the combined effects of avertin and amylene hydrate are being considered.

Amylene hydrate, introduced as a sedative by Harnack and Meyer in 1894, is a tertiary amyl alcohol, $(CH_3)_2C(OH)C_2H_5$. It ranks between chloral hydrate and paraldehyde in hypnotic properties, and is fairly nontoxic. It is a colorless fluid, soluble in eight parts of water, and readily soluble in glycerin. The hypnotic dose is one to four grams, administered in glycerin, but the drug is almost never used clinically for the purpose of sedation. The amount of amylene hydrate contained in avertin with amylene hydrate given to a 60 kg man, at the dose level of 80 mgm of avertin per kg, is only 2.4 grams, and therefore the depressant action of the solvent *per se* cannot contribute much to the anesthesia.

Actions. Avertin has the typical depressant action on the central nervous system of the methane series of anesthetics.

Induction. Induction of anesthesia following the rectal administration of avertin is fairly rapid and quite pleasant, and usually there is little or no excitement stage. The patient often merely "falls asleep" within five to 15 minutes, without being disturbed by a face mask, machinery or unpleasant vapors. The anesthetic can be given in the patient's room, often without telling him that he is being prepared for surgery. This feature is sometimes of great value in the thyrotoxic patient, to whom the rectal anesthesia can be administered as a "routine enema."

Basal Anesthesia. Maximal basal anesthetic action is reached in from 20 to 30 minutes, at which time the concentration of avertin in the blood is from six to 10 mgm per cent. The anesthesia becomes lighter by the end of one hour, and consciousness is regained in from one and one-half to three hours, at which time the concentration of avertin in the blood has fallen to two or three mgm per cent. Awakening is usually followed by a long postoperative sleep, lasting for several hours, and complete amnesia exists for this entire period.

Muscular Relaxation. The muscular relaxation obtained with avertin varies with the dose of anesthetic given. It is quite complete with large doses which produce deep surgical anesthesia, but is only partial with safe doses which produce only plane i anesthesia. Excellent relaxation occurs when slight amounts of supplemental ether or cyclopropane are used with basal anesthetic doses of avertin.

Circulation. Avertin usually causes an early, rather marked but temporary fall in blood pressure, which varies from 15 to 40 mm of mercury, averaging about 25 mm. Occasionally, as in cases of hypertension, the systolic pressure may fall 100 mm of mercury. The hypotension lasts only five to 15 minutes and is rarely dangerous. It may easily be combated with ephedrine which may in certain cases be given prior to the avertin. The decline in blood pressure is due to depression by avertin of the medullary vasomotor centers, as well as to some degree of direct depressant action on the heart and blood vessels. Myocardial depression due to avertin is clinically negligible when basal anesthetic doses are employed. Perfusion experiments indicate that the drug is only one-sixteenth as toxic as chloroform to the mammalian heart.

Respiration. The respiration is markedly depressed by full anesthetic doses of avertin, and respiratory arrest is the major danger in avertin anesthesia. The usual cause of death with avertin is respiratory paralysis; but, when proper doses for basal anesthesia are given, avertin rarely causes serious respiratory embarrassment. Avertin is a solid anesthetic and there is no rapid way in an emergency to reduce its concentration in the body. Once given, it is beyond the fine control of the anesthetist. It is thus not safely used alone for complete surgical anesthesia, but is employed mainly for basal anesthesia with supplemental ether, nitrous oxide or cyclopropane. When breathing ceases, due to overdosage, artificial respiration can do no more than maintain oxygenation of the blood and does not, as is the case with volatile anesthetics, promote the pulmonary excretion of the toxic agent. Because of respiratory depression arising from avertin, preliminary morphine should not be used unles given in small doses (eight mgm) fully one and one-half hours beforehand. If the depression of breathing due to basal anesthesia with avertin is marked, pulmonary exchange may be too greatly diminished to allow induction of the proper plane of surgical anesthesia with an inhalation anesthetic (page 37) unless carbon dioxide is administered. It should be a rule not to use avertin as a basal anesthetic unless a person capable of intubating the trachea is available (Beecher, 1938).

Avertin tends to produce marked relaxation of the jaw muscles and obstruction of the airway may result. A rubber or metal airway should be inserted as soon as basal anesthesia is complete and not removed until the patient fully awakens.

Metabolic Effects. When avertin is used for basal anesthesia, the metabolic disturbances are mild as a rule. The body temperature is somewhat lowered, the blood sugar slightly elevated, and the CO_2-combining power of the blood slightly decreased. The basal metabolic rate is lowered by an average of 15 per cent.

Liver. Doses of avertin used in basal anesthesia have little serious effect on the normal liver. A detectable functional deficiency, as determined by the bromsulfalein dye excretion test, however, can be shown to occur more frequently after avertin than with ether or nitrous oxide anesthesia (Coleman, 1938). Large doses of avertin in normal persons, or smaller amounts in patients with liver disease, may possibly cause hepatic damage. In animal experiments, large repeated doses are required to produce liver damage which is only moderate in degree and reversible (Bourne and Raginsky, 1931). Although avertin has been given to jaundiced patients with apparently no ill consequences, by far the safest procedure is to limit its use to those with normal liver function. The rôle played by the healthy liver in detoxifying tribromethanol and removing it from the tissues is emphasized by the perfusion experiments cited by Beecher (1938). A 420 gram normal liver of a dog reduced the blood concentration of avertin from 130 mgm per cent to six mgm per cent in 90 minutes, whereas a liver in which fatty degeneration was experimentally produced was only about half as efficient. This is in agreement with the clinical finding that dangerously prolonged anesthesia may occur from avertin in patients with disease of the liver.

Kidneys. Avertin may cause albuminuria and frank renal injury may occur if the drug is used in patients with renal disease. Abnormally long and deep anesthesia may result if avertin is employed when renal function is poor because the kidneys represent the obligatory route of excretion. Renal insufficiency lowers considerably the margin of safety of the drug (Veal and coworkers, 1931).

Postanesthetic Recovery. Recovery from avertin anesthesia is pleasant as a rule, the patient awakening as from sleep. Nausea and vomiting are less frequent than with ethylene or ether, the incidence being about 22 per cent (Wood, 1936).

Absorption, Fate and Excretion. The rectal absorption of avertin dissolved in amylene hydrate is rapid. Fifty per cent is absorbed within 10 minutes, 75 per cent within 20 minutes, 85 per cent within 25 minutes and from 90 to 95 per cent within two hours. These figures, however, represent only approximate averages because the rate of absorption varies widely. For example, Sebening (1932) found that one patient absorbed 38 per cent within 10 minutes; another only 11 per cent within 60 minutes; the first subject absorbed a total of 80 per cent, the second only 29 per cent. When it is appreciated that the anesthetic action depends more on the rapidity of absorption than on the final amount absorbed, the variation in response to avertin can readily be understood. Avertin is combined with glycuronic acid in the liver, and its detoxification is therefore impaired when hepatic function is diminished. This constitutes another reason for caution in using avertin in patients with any suggestion of liver damage.

Avertin-glycuronate is excreted quantitatively by the kidneys, and quite rapidly. Excretion lags only slightly behind absorption and the drug is almost entirely eliminated by the end of two hours. Therefore avertin cannot be used alone for prolonged operations. If kidney function is poor, excretion may be considerably delayed and the toxicity of avertin correspondingly enhanced. Nephritis therefore is a definite contraindication to the use of avertin.

Administration and Dosage. *Preliminary Medication.* Atropine and morphine are usually given prior to avertin, but the dose of morphine must be reduced to eight or 10 mgm and given one and one-half hours before the avertin. Some believe that scopolamine should not be employed with morphine prior to avertin.

Dosage. Proper dosage is all important in the safe use of avertin for basal anesthesia. In the average case, a dose of 50 to 60 mgm per kg of avertin causes drowsiness, sleep, and amnesia; 70 to 80 mgm per kg results in light unconsciousness and analgesia; 90 to 100 mgm per kg causes complete anesthesia with varying degrees of muscular relaxation and loss of reflexes. The last mentioned dose, however, results in satisfactory surgical anesthesia in only 20 per cent of patients. Doses of 125 to 150 mgm per kg raise this figure only to 50 or 60 per cent. Inasmuch as the range of safe dosage extends only to 100 mgm per kg, it is clear that avertin alone should not be used for complete surgical anesthesia. Even the dose of 100 mgm per kg may sometimes produce complete and not basal anesthesia. The Council (1937) has recommended a dose of 80 mgm per kg as the ordinary maximum.

Total dosage, as a rule, is based on the weight of the patient. Some anesthetists, however, use the surface area of the body in calculating the dose. Charts are available for rapidly ascertaining the dose on the basis either of body weight or surface area, but these charts should not replace the anesthetist's judgment as to the special needs of the particular case. Regardless of the patient's weight, a total dose of nine to 10 grams for men, or six to eight grams for women is not exceeded. Dosage is reduced for elderly or cachectic patients, and is never over 60 to 80 mgm per kg in obese patients, hypertensive or arteriosclerotic individuals or those with chronic debilitating or degenerative diseases.

Children are definitely more tolerant to avertin, but nevertheless the same dose scale is used as for adults. If the basal anesthesia is insufficient, however, more supplemental anesthesia should be used rather than an increase in the dose of avertin. Boyd (1935) reported 700 cases without fatality in which avertin was employed as a complete anesthetic in children, in doses of 175 mgm to 200 mgm per kg; but in 2.5 per cent of his patients, stimulation of respiration or circulation was required. The use of avertin for full surgical anesthesia in children should not be countenanced, despite occasional reports of success.

The patient's reflex irritability is of importance in calculating the dose of avertin. For example, each of two patients may be given 80 mgm per kg of the drug. One with low reflex excitability may be asleep within a few minutes, while the other with a high level of reflex excitability remains in a state of restless delirium. If the first patient had received 60 mgm per kg and the second patient 100 mgm, both would be in approximately the same state of basal anesthesia.

Technic. Avertin with amylene hydrate is administered only by rectum. A cleansing enema is given beforehand. The properly prepared avertin solution is allowed to flow gently by gravity (from a height of two feet) through a rectal

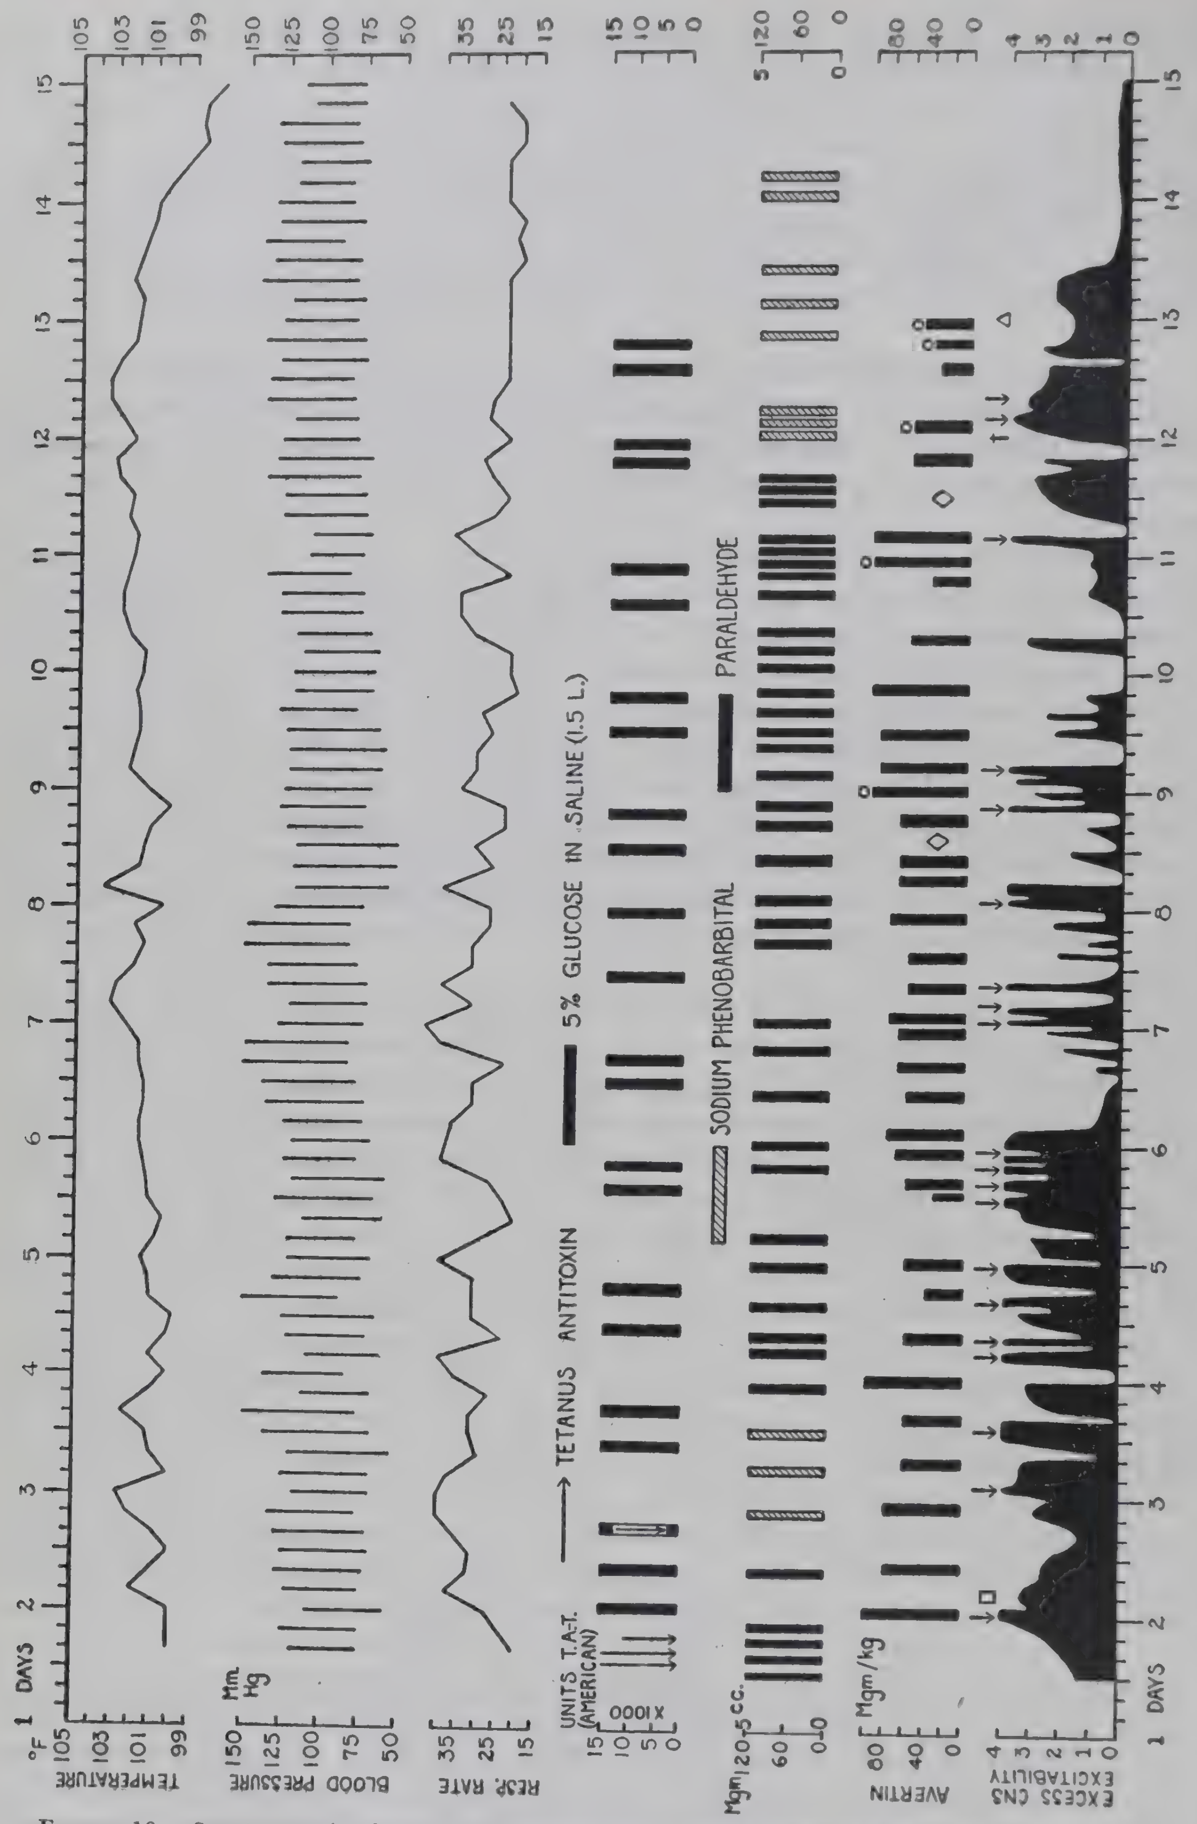

Figure 10. *Symptomatic therapy of tetanus with central nervous system depressants.*

Mechanic, aged 26, weight 82 kg. Patient admitted to hospital three days after sustaining a lacerating wound of the right index finger. Examination showed stiffness of the neck, hyperactive deep reflexes, trismus and spontaneous mild tonic spasms of various muscle groups. Within a few tube introduced into the lowest part of the bowel. The avertin is given 20 minutes or more before operation is contemplated. Fully three to five minutes should be allowed for the administration. High and rapid injection may cause speedy absorption and undue depression of the respiration and blood pressure.

The calculated dose of avertin in amylene hydrate is dissolved in approximately 40 volumes of distilled water or physiological sodium chloride solution, previously heated to exactly 40 C., and shaken vigorously until all globules of avertin liquid have disappeared. Above 40 C., hydrobromic acid and dibromacetaldehyde may be liberated, and these compounds can cause severe injury to the rectal mucous membranes. The avertin with amylene hydrate should go entirely into solution and if crystals of avertin appear, the mixture must be discarded. Congo red solution is supplied with each bottle of avertin, and is used to test the pH of the anesthetic mixture. If the avertin solution is too acid, it must not be used because it is decomposed and dangerous. The anesthetic solution is administered before cooling occurs. Details must be rigidly observed as improper technic may result in severe reactions, such as hemorrhagic proctitis. Diseases of the rectum and sigmoid obviously contraindicate the use of avertin.

Advantages of Avertin as a Basal Anesthetic. Avertin has the advantages of ease of administration and pleasant induction. The mental distress and respiratory irritation incident to the use of several inhalation anesthetics are avoided. Postoperative sequelae are few and the incidence of nausea and vomiting is not high. Basal anesthesia with avertin decreases by one-half the amount of inhalation anesthetic subsequently needed. The resultant depressant effects, however,

---

hours, the patient's condition rapidly became worse and three severe generalized convulsive seizures occurred in rapid succession. Patient remained unconscious from the onset of symptomatic therapy with avertin until the eleventh hospital day. Within the first 28 hours, 40,000 units (American) of tetanus antitoxin were injected intramuscularly, and 10,000 units intravenously. Nutrition, body water and electrolytes were maintained purely by means of intravenous infusions of glucose and saline. Body weight fell 14 kg. The attempt was made to control the extreme hyperexcitability of the nervous system by the intramuscular injection of paraldehyde and sodium phenobarbital and the rectal instillation of avertin in amylene hydrate, in amounts and at intervals shown in the figure. The degree of success obtained is depicted in the solid black area at the bottom which indicates, on an arbitrary scale, the degree of excess nervous system excitability. The zero line does not represent normality but rather the absence of convulsive phenomena. Even when the patient was completely anesthetized, motor restlessness and tonic spasms occurred at times.

Observe that paraldehyde and sodium phenobarbital were considerably less effective than tribromethanol in giving symptomatic relief, but even deep anesthesia with avertin did not annul the neuromuscular phenomena characteristic of tetanus. This suggests that tetanus convulsions differ in point of origin from those produced by convulsant drugs (Harvey, 1939). Over a period of 12 days, 38 injections of paraldehyde were given (190 cc), 11 of phenobarbital (1.3 grams), and 36 doses of avertin totalling (exclusive of enemas in part expelled) 2070 mgm per kg or 170 grams.

Despite the large amounts of avertin, urobilinogen tests revealed no liver damage, and bromsulfalein dye excretion tests performed on the 22nd and 29th day resulted in normal figures. The blood pressure and respiratory rate, as well as the temperature, throughout the course of the illness are also shown in the chart. Note that the cardiovascular and respiratory systems were not adversely affected by the large amount of depressant drug medication. (Case data through courtesy of Dr. B. S. Brody, Yale University School of Medicine.)

are probably only additive. The long postanesthetic period of sedation is of special value in cases of brain surgery and severe hyperthyroid disease. It lasts several hours and obviates the need of analgesics and hypnotics.

Special Uses of Avertin as a Basal Anesthetic. In thyrotoxic patients who are extremely nervous and apprehensive, once the written consent of the patient for operation is obtained, avertin can be given without the patient knowing that he is scheduled for surgery. In patients with pulmonary disease, avertin has the advantages that it is not excreted by the lungs and that it greatly reduces the amount of inhalation anesthetic necessary. In cases of brain surgery, inhalation anesthesia generally raises the cerebrospinal fluid pressure. Avertin, on the other hand, tends to lower intracranial pressure, and has been found particularly suitable for neurosurgery. The fall in cerebrospinal fluid pressure noted in animals under avertin anesthesia (Seevers and associates, 1931; Finesinger and Cobb, 1935) agrees with the clinical experience of neurosurgeons using avertin basal anesthesia. For biopsy procedures in patients with questionable malignant growths, avertin removes apprehension by keeping the patient asleep while the frozen sections, pathological examination, diagnosis and consultation are being made. If radical surgery is decided upon, the patient is already under basal anesthesia.

Avertin in Convulsive States. Avertin may at times be effectively employed for the symptomatic therapy of certain convulsive states including tetanus, status epilepticus and eclampsia. It may also be useful in controlling maniacal patients. For the convulsions of tetanus, avertin can be given repeatedly over a period of many hours or several days. As many as 30 doses of 60 to 80 mgm per kg each have been administered to patients for the control of severe convulsions. In one instance, 170 grams were given over a 12 day period. Recovery followed, and no liver damage developed (Figure 10). The dose of the drug is reduced and the interval between doses is increased as improvement occurs.

Disadvantages. The chief disadvantage of avertin is that it is a fixed, nonvolatile anesthetic. The anesthetist therefore lacks adequate control once it is administered. Avertin is a halogenated hydrocarbon and thus has the potentiality for damaging parenchymatous organs. Differences in the rates of absorption and excretion of avertin may cause marked variations in the depth and duration of anesthesia. Avertin is safe only in doses producing basal anesthesia and therefore a second anesthetic agent is required. Experience shows that the toxicity of anesthetic combinations is that of the most toxic member, and this fact demands careful selection of the supplemental agent. Constant nursing is required from start to recovery of avertin anesthesia, and also during the long postanesthetic sleep. Under many circumstances, a prolonged postanesthetic sleep is not desirable. Avertin anesthesia is limited to operations of moderate length, due to the rapid rate of excretion of the drug, and greater increments of supplemental anesthesia must be used if the operation is prolonged.

Contraindications. Addicts to alcohol manifest cross-tolerance to avertin; therefore the basal anesthetic dose is difficult to judge and may need to be so large that injury to parenchymatous organs may result. The presence of hepatitis, cirrhosis, and jaundice usually contraindicates the use of avertin, because of the possibility of further damage to the liver and for the reason that the liver plays an important rôle in the detoxification of the drug. Patients with nephritis should not receive avertin, because the kidney is the obligatory channel of excretion and further renal damage may occur. Although avertin has been used apparently with safety in persons with chronic low-grade renal impairment, acute or severe renal insufficiency is an absolute contraindication. In diseases of the rectum and colon, such as tumors, enteritis, ileus, obstruction, etc., avertin anesthesia should not be used. The drug should not be administered to hypotensive or hypertensive patients unless ephedrine or benzedrine is used to prevent a marked fall in blood pressure. Patients with poor respiratory exchange due to far advanced pulmonary disease should not receive avertin, and it is also wise not to use it for those with severe heart failure, acidosis, toxemia, shock, severe sepsis, anemia and marked hypothyroidism. Although avertin tends to cause uterine atony, it has been employed in the second stage of labor; but even low doses (60 mgm per kg) which cause only analgesia and amnesia may delay labor and make the patient unmanageable. Larger amounts may seriously depress the fetal respiratory mechanism. The drug is not advisable in obstetrics.

Lack of experience with avertin is a final contraindication to its use. Shipway (1935), in discussing his experience with 1600 administrations of avertin, says, "The practitioner who is called upon to administer anesthetics on few and irregular occasions, or is but a beginner at this arduous and hazardous speciality, will be well advised to leave avertin severely alone."

Antagonists. In case the anesthetic action of avertin becomes too profound, pharmacological antagonists may be needed. Treatment consists in the use of agents which stimulate the respiratory and vasomotor centers, lessen the intensity of the anesthesia and raise the blood pressure. Carbon dioxide, ephedrine, picrotoxin, metrazol, and caffeine with sodium benzoate are helpful. If shallow respiration and feeble pulse appear early as an index of overdosage, the washing out of the rectum to remove the unabsorbed avertin is a procedure not to be scorned. Other aids will be found under the discussion of the treatment of barbiturate and morphine poisoning (pages 142, 210).

CHAPTER 8

THE ALCOHOLS

ETHYL ALCOHOL

Alcoholic beverages have been used since the dawn of history and the opinions and traditions of the past often cloud the discussion of this subject. Alcohol was formerly believed to be a remedy for practically all diseases. This is indicated by the term "whisky" (Gaelic: "usquebaugh," water of life). It is now recognized that the therapeutic value of alcohol is much more limited than is its social value.

Pharmacological Actions

Local. Alcohol injures cells by precipitating and desiccating protoplasm. This results in the shrinkage of tissue and alcohol is thus an astringent. It is also an irritant to denuded skin and to mucosa. The more concentrated the alcohol, the more pronounced are its effects. The use of alcohol for hardening and dehydrating tissues preparatory to histological section provides a familiar instance of the local action of alcohol.

Skin. Alcohol causes cooling of the skin by evaporation. Alcohol sponges are therefore commonly employed in fevers. Alcohol rubbed on the skin produces mild redness and burning, and therefore it is employed as a counter-irritant and rubefacient. It is routinely used in bedridden patients to prevent bedsores and decubitus ulcers, for it hardens and cleans the skin and helps to prevent sweating.

Mucous Membrane. The irritant action of alcohol is marked on mucosae. The use of strong solutions may result in considerable inflammation. For example, chronic gastritis and enteritis are not uncommon in steady drinkers.

Subcutaneous Tissue. Alcohol injected hypodermically causes considerable pain followed by anesthesia. If the injection is made close to nerves, degeneration may occur. Injections in or near nerves are deliberately used to cause anesthesia of protracted or even permanent character in the treatment of severe pain, especially in sciatica or tic douloureux.

Action on Bacteria. The optimal bactericidal concentration of alcohol is 70 per cent *by weight* (Price, 1939). Alcohol in concentrations varying only slightly from this optimal value are definitely less effective. A concentration of alcohol below 60 per cent or above 80 per cent cannot be depended upon to exert any antiseptic action, probably due to the fact that solutions of these strengths do not readily penetrate protein. Indeed, Price found that 70 per cent alcohol by volume is almost useless as a germicide. Inasmuch as alcohol by weight has no constant volume per cent equivalent, Price has described a relatively simple method for preparing a 70 per cent concentration by weight from commercial alcohol. Very high concentrations of alcohol may dehydrate bacteria without killing them.

Systemic Actions

After absorption, alcohol in sufficient amount affects nearly every tissue of the body, but in particular the nervous system.

Central Nervous System. The question whether alcohol is a "stimulant" has long been debated. Laymen in particular view alcoholic drinks as stimulating. It may be stated categorically that alcohol is not a stimulant but rather a primary and continuous depressant of the nervous system. In this respect it shares the characteristic action of the general anesthetics. The apparent stimulation results from the unrestrained activity of lower centers freed by the depression of higher inhibitory control mechanisms. A familiar example of this is seen in the excitement stage of anesthesia.

Psychic Effects. Horace wrote, "What wonders does not wine! It discloses secrets; ratifies and confirms our hopes; thrusts the coward forth to battle; eases the anxious mind of its burden; instructs in arts. Whom has not a cheerful glass made eloquent! Whom not quite free and easy from pinching poverty!"

The psychic phenomena which follow the ingestion of alcohol arise from an inhibition or depression of higher mental processes, especially those depending on training and previous experience and which usually make for sobriety and self-restraint. The finer grades of discrimination, memory, concentration and insight are dulled and then lost. Impulsive speech and actions result, and inhibitions are removed. Confidence abounds, the personality becomes expansive and vivacious, and speech may become eloquent and occasionally brilliant. Mood swings are uncontrolled and emotional outbursts frequent. The individual may believe himself powerful enough to whip several strong men even when it takes this number to hold him upon his feet. The particular type of behavior manifested under the influence of alcohol is the resultant of three factors,—the personality of the individual, tolerance for the drug, and extraneous stimuli including those provided by the presence of others. Drinking is usually done in company and much of the hilarity, joviality and excitement is dependent upon mutual stimulation.

Carefully performed experiments have shown that alcohol increases neither the mental nor physical abilities. Although the individual estimates his own performance as greatly improved, in reality actual measurement shows it to be inferior. The tests have been concerned with typewriting, target practice, etc., as well as with complicated mental problems, and all the results indicate decreased efficiency. Familiar and habitual tasks, especially if mechanical in nature, are less markedly affected than is work requiring skill, thought and attention.

Brain and Cord. Alcohol is an irregularly descending depressant of the central nervous system. General anesthesia from alcohol lasts much longer than that from chloroform or ether, due to the slow oxidation and delayed excretion of alcohol. Alcohol differs from the volatile anesthetics in that over 90 per cent of it is destroyed in the body. There is little margin between the anesthetic and fatal doses. For these reasons, alcohol is not employed as a general anesthetic.

As an anesthetic, alcohol occupies a place between the general anesthetics and the hypnotics. It is still occasionally used as an analgesic and hypnotic, but much more so by the laity than by the medical profession.

Respiration. There is no clear evidence that the respiratory center is stimulated by ordinary doses of alcohol. Depression of respiration does not occur, however, except late in the course of marked alcoholic intoxication. Respiratory effects from clinical doses of alcohol are negligible and ancertain.

Cardiovascular System. The blood pressure does not change significantly after moderate amounts of alcohol. The pulse rate may increase, but this is usually secondary to muscular activity. The cardiac effects are slight and inconstant, and difficult to attribute to alcohol. Any claim that the force of the heart beat is increased by alcohol is certainly not proved. High concentrations of alcohol depress the heart, but this toxic action is less marked than with chloroform or ether. For example, the beat of the excised mammalian heart is stopped within two minutes when the organ is perfused with 0.15 per cent chloroform, but is not noticeably affected by two per cent alcohol. Much lower concentrations of alcohol (0.10 to 0.30 per cent), however, definitely decrease the total energy output of the heart (Peters and associates, 1936). Central vasomotor factors undoubtedly contribute to the cardiovascular depression in late alcohol poisoning.

Alcohol causes vasodilatation, especially of the cutaneous vessels, and produces a warm and flushed skin. Vasodilatation may be a central vasomotor effect because the direct action of alcohol on vessels is insignificant. The vasodilatation produced by alcohol is utilized in the treatment of certain peripheral vascular diseases. Most cardiologists agree that the coronary arteries are dilated by moderate doses of alcohol and that alcohol is not an etiological factor in angina pectoris (White and Sharker, 1934). Some consider alcohol to be the best drug in the treatment of angina pectoris. The "quieting effect" of alcohol on the pulse of patients with fever results from a central depressant rather than from a peripheral cardiac action.

Body Temperature. Although one feels warm after ingestion of alcohol, due to the increased cutaneous and gastric blood flow, heat loss increases and internal temperature falls. Increased sweating may occur and enhance the heat loss. Only with large amounts does the fall in body temperature become pronounced and this effect is then also due to the depression of the central mechanism which regulates temperature. The action of alcohol in lowering body temperature is naturally greater when the environmental temperature is low, or when the mechanism dissipating heat is disturbed, as during fever. The taking of alcoholic beverages to "keep warm" in cold weather is obviously irrational, and may be dangerous if the conservation of body heat is essential. Those experienced in polar exploration are well acquainted with these facts.

Gastro-intestinal Tract. The effects of varying concentrations and types of alcoholic beverages on the gastro-intestinal motor and secretory functions are influenced by a number of factors. Among these are the state of the digestive processes, the presence or absence of gastro-intestinal disease, the amount and type of food present, the degree of tolerance for alcohol, accompanying psychological factors, etc. Salivary secretion is usually stimulated reflexly by alcohol. If the individual likes alcohol, a secretion of appetite juice rich in acid will ensue. The presence in the stomach of alcohol in concentrations of approximately 10 per cent results in a gastric secretion rich in acid but poor in pepsin. An alcohol meal is thus employed as a functional test for the ability of the gastric glands to secrete free hydrochloric acid. Although pepsin is decreased in amount, peptic digestion is not interfered with by low concentrations of alcohol. Also gastric motility is not impaired. Alcohol stimulates gastric secretion by a reflex action. When it is placed in the stomach of a Pavlov pouch dog, the gastric pouch manifests typical secretory activity.

As the concentration of alcohol in ingested beverages is elevated approximately to 20 per cent and above, secretion tends to be inhibited and peptic activity is depressed. Malt liquors and wines, even in lower concentration, cause a similar inhibition. This is due mainly to the colloidal substances, tannins and organic acids which they contain rather than to their content of alcohol. Strong alcoholic drinks of 40 per cent strength and over are quite irritating to the mucosa and cause congestive hyperemia and inflammation. The presence of food tends to decrease the concentration of alcohol and lessen irritation, and the stomach itself secretes protective mucus. The long-continued use of strong alcoholic beverages may result in chronic gastritis. Achlorhydria is common in chronic alcoholism. A small amount of concentrated alcohol may act as a carminative.

Alcohol apparently has little deleterious effect on the intestinal or pancreatic secretions. Intestinal digestion is not likely to be impaired and the secretion of pancreatic juice may be stimulated by small doses of alcohol. Alcohol which reaches the intestine is diluted by gastric secretions and mucus. No one contends that the use of *large* amounts of alcohol is without serious effects on gastro-intestinal function. The crucial problem centers about the use of moderate amounts of alcoholic drinks. If one enjoys alcohol, small amounts cannot be considered deleterious, and may affect digestion favorably if taken with meals. The influence of alcohol on the digestive tract has been extensively reviewed by Beazell and Ivy (1940).

Kidney. Alcohol increases the flow of urine. This is caused not by any potent diuretic action of alcohol but rather by the large amounts of fluid ordinarily ingested while drinking alcoholic beverages.

High concentrations of alcohol may injure the renal epithelium, especially if there is pre-existing kidney damage, although this point is disputed. It is difficult to attribute to alcohol alone the renal disease occurring in addicts. It has been stated, however, that the kidneys of habitual drinkers are not normal. Most pathologists disagree with the implications of this statement and there is considerable evidence to show that the incidence of nephritis is not exceptionally high in addicts, and that alcohol does not further damage the kidney in patients with Bright's disease. The experiments of Bruger, Localio and Guthrie (1939) are significant in this connection. They performed Addis counts, urea clearances and careful blood and urine studies in normal subjects, in patients with acute and chronic diffuse nephritis, and in patients with arteriosclerotic nephritis before and after the ingestion of varying amounts of alcohol or whisky. In patients with acute or chronic nephritis, proteinuria was rarely augmented; the number of red blood cells and casts in the urine was not increased and renal function was not changed. In subjects with arteriosclerotic nephritis, however, a transient increase in the Addis count and temporary decrease in renal function were caused by alcohol. In normal persons, whisky or alcohol had no deleterious effects on the kidneys. The effects of alcohol on the normal and pathological kidney have been reviewed by Bruger (1940).

Sexual Functions. It is a popular notion that alcohol is an aphrodisiac. Shakespeare, however, realized that inebriation interfered with coitus. In Macbeth, for example, the following conversation occurs (Act 2, scene 3):

Macduff: What three things does drink especially provoke?
Porter: Marry, sir, nose-painting, sleep, and urine. Lechery, sir, it provokes, and unprovokes; it provokes the desire, but it takes away the performance. . . .

Loss of inhibition and restraint is the cause of the sexual behavior seen after alcohol.

Skeletal Muscle. Alcohol is not a true stimulant of muscular activity. From some experiments, it would appear that the total amount of work accomplished may be increased under the influence of small doses of alcohol but this is largely due to a lessened appreciation of fatigue. Alcohol is also a readily available source of energy for muscular work. Furthermore, vasodilatation may improve the circulation in muscle. There is little reason to believe, therefore, that alcohol has any direct effect on muscle contractility. Large doses of alcohol decrease the amount of muscular work accomplished. This is due to the central nervous system depression. The opinion that moderate doses of alcohol directly depress muscle is unsupported by acceptable evidence.

Absorption, Fate and Excretion of Alcohol. *Absorption.* Alcohol is rapidly absorbed from both the stomach and intestine. The stomach usually absorbs about 20 per cent of the ingested alcohol and the intestinal tract the remainder. Most of the alcohol gains entrance to the body through the jejunum and absorption is usually completed in two and one-half hours. The rate of absorption varies directly with the concentration. It is well known that alcohol taken as whisky is more readily absorbed than the same amount taken as beer. Many factors may retard gastro-intestinal absorption of alcohol. That food is a most important factor is obvious from the difference in effects obtained by drinking a cocktail before dinner as contrasted with its effects when taken after dinner. Experienced drinkers therefore take food with their drinks.

Absorption of alcohol occurs readily through the colon. Vaporized alcohol can be absorbed through the lungs. Intoxication and even death may ensue from the inhalation of alcohol. Subcutaneous absorption is also rapid, if the concentration of alcohol is not too high. It is doubtful whether absorption occurs through the skin.

Distribution. Alcohol differs from most foods in that it is unchanged in the intestines and is absorbed as such. All organs and fluids of the body contain alcohol within a few minutes after it is ingested. It also gains ready access to the fetal circulation. The distribution of alcohol in various tissues is fairly uniform. However, the concentration of alcohol in the brain and spinal fluid is slower in rising and falling than that in other tissues. A similar delay in equilibration occurs in the case of bromide. The amount of alcohol found in the brains of patients dying of alcoholic intoxication varied from 0.27 to 0.51 per cent (Gettler and Tiber, 1927).

Oxidation. Ninety to 99 per cent of alcohol is almost completely burned in the body. In the process of oxidation, energy is released and carbon dioxide and water are produced. The rate of oxidation is thought to be fairly constant regardless of the amount of alcohol present in the tissues, at least as measured by the rate of its disappearance from the blood. For example, if the amount of ingested alcohol is increased 100 per cent, the rate of disappearance of alcohol from the blood is accelerated by only 17 per cent (Newman and coworkers, 1937). When large amounts of alcohol are given, oxidation may be incomplete and aldehydes, acetic acid and other substances are thought to be formed as intermediary products. These may appear in the breath and urine. Haggard, Greenberg and Cohen (1938) suggest from their experiments that the rate and completeness of oxidation of alcohol vary with different types of beverages. For example, two whiskies with equal alcoholic content may require widely varying periods for oxidation. The nature of the substances which account for this phenomenon is undetermined.

The amount of alcohol oxidized per unit of time varies somewhat with the individual. Studies on man (Higgins, 1917) indicate that approximately 3.5 cc of alcohol are burned per hour. At this rate approximately eight hours would be required for the oxidation of one ounce of alcohol. However, on the basis of experiments on dogs, Mellanby (1919) calculates that a man of average weight can burn about 10 cc of alcohol per hour. Other figures vary from six to 15 cc per hour. Atwater and Benedict (1902) concluded that 90 cc of alcohol taken in the form of six ounces of whisky require approximately six hours for oxidation. The rate of combustion in persons habituated to alcohol as compared to that in occasional drinkers is not known, although it appears to be the same despite the fact that the blood level falls faster in the former group. If the rate of combustion of alcohol in man is accepted as 10 cc per hour (approximately eight grams), 56 calories per hour can be supplied in this manner.

The liver is probably the chief site of the initial oxidation of alcohol, and insulin appears to be necessary for this function. Clark and coworkers (1939) have shown that depancreatized dogs and cats receiving no insulin oxidize alcohol at a rate very much below normal. Also, hepatectomized animals oxidize alcohol at a rate comparable to that in the depancreatized preparations, and injections of glucose and insulin did not hasten the rate of disappearance of alcohol. Thus oxidation of alcohol in the liver under the influence of insulin is strongly suggested. Indeed, the investigations of Goldfarb, Bowman and Parker (1939) support the view that there is a definite relation between the oxidation of alcohol and the oxidation of glucose. They studied a series of alcoholic patients with a history of drinking and presenting various degrees of intoxication. The subjects were classified in four groups and managed as follows: (1) no therapy; (2) subcutaneous injection of 15 units of insulin; (3) intravenous administration of 50 cc of 50 per cent glucose; (4) simultaneous administration of insulin and glucose in the above doses. The blood alcohol levels were then followed and the rapidity of the emergence from intoxication noted. Insulin therapy alone had no effect on the disappearance of alcohol from the blood. Glucose alone hastened the reduction in blood alcohol levels only in the more severely intoxicated patients. Therapy with glucose plus insulin accelerated recovery in both moderately and severely intoxicated patients. Consciousness was regained within one and one-half to two hours, at which time a rational history was usually obtainable, and some subjects showed adequate motor co-ordination within four to five hours. Goldfarb, Bowman and Parker suggest that the oxidation of alcohol may be catalyzed by the simultaneous oxidation of glucose. This treatment of acute alcoholism appears promising, and the immediate attendance of the physician is required for only a brief time (Figure 11).

Excretion. Normally, about two per cent of ingested alcohol escapes oxidation and is excreted. Under special circumstances and when large doses have been consumed, this figure may be as high as 10 per cent. Alcohol leaves the body mainly through the kidneys and lungs, but it can also be detected in sweat, tears and other secretions.

The amount of alcohol eliminated through the lungs ordinarily is less than 0.5 per cent and rarely exceeds two per cent of that ingested. The "strong" odor imparted to the breath is mainly due to other volatile constituents of the beverage. The concentration of alcohol in the expired air parallels at a much lower level that in the blood and has been used extensively as an index of the amount of alcohol in the blood and tissues. An intoxicated person may excrete several milligrams of alcohol per liter of air, and one gram per hour may escape in this way if respiratory minute volume is increased by excitement, exercise or inhalation of carbon dioxide. Hyperpnea induced by carbon dioxide has been used to hasten excretion by the lungs and bring patients out of alcoholic coma, but it is doubtful whether recovery is hastened by the slight additional excretion of alcohol.

The concentration of alcohol in the urine also varies with that in the blood.

The urine of an intoxicated person may contain as much as five grams per liter. The total renal excretion of alcohol, however, rarely exceeds three per cent of that ingested, and within eight hours as a rule the urine is free of alcohol. Some reabsorption of alcohol occurs from the bladder epithelium when the urine concentration is much higher than that of the blood. Alcohol is one of the few substances which the normal bladder mucosa can absorb.

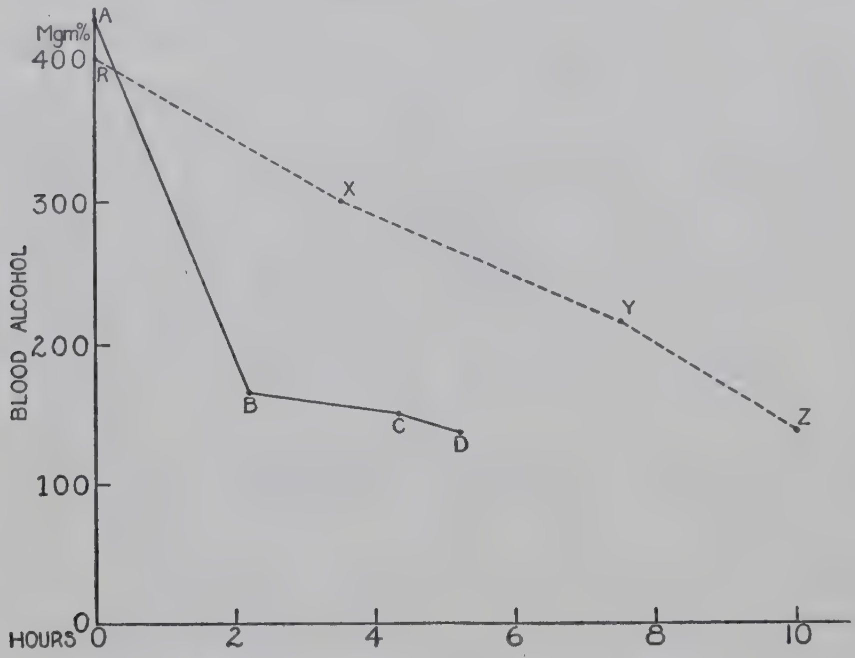

FIGURE 11. *The effect of glucose and insulin on the recovery from acute alcoholic intoxication.*

Two patients, both chronic drinkers, suffering from acute alcoholic intoxication with blood alcohol levels approximately 400 mgm per cent at the time of admission to the hospital. *Solid line,* blood alcohol curve of patient who at zero time was given an intravenous injection of 50 cc of a 50 per cent solution of glucose and 15 units of insulin. *Broken line,* blood alcohol curve of patient receiving no treatment. At *A;* the treated patient could not be awakened but groaned and struggled in response to stimulation; at *B,* he was aroused by the stimulus of a venepuncture and was oriented and clear; at *C,* he was awake, oriented and mentally clear; at *D,* he requested discharge and was able to walk without difficulty. At *R,* the untreated patient was comatose and did not respond readily to stimuli; at *X,* he was aroused by the stimulus of a venepuncture but dysarthria, confusion and disorientation were prominent; at *Y,* the patient was awake but flushed and nauseated, and he was not well oriented until the tenth hour (*Z*). It is clear that glucose and insulin therapy causes a rapid fall in the concentration of blood alcohol and results in clinical recovery at a time when the untreated patient is still intoxicated. Note that chronic drinkers are well oriented at blood alcohol levels which would be associated with drunkenness in the occasional drinker. (Drawn from case data supplied through the courtesy of Dr. Walter Goldfarb.)

Much attention has been given to the relation between the urine and blood levels of alcohol. It has been contended that the urine concentration is the same, for practical purposes, as the blood concentration and that differences may be accounted for on the basis of time elapsed in urine formation and excretion. It is difficult to reconcile this belief with the modern concept of the mechanism of urine formation unless it is assumed that alcohol and water are reabsorbed in the same proportion by the renal tubule. Others contend that the blood values are uniformly and significantly lower than those of the urine (Miles, 1922). Southgate and Carter (1926) found the urine: blood ratio to be 1.35:1.0. The urinary alcohol levels can be used to indicate the blood and tissue concentration (Table 3).

Only traces of alcohol are found in the other secretions of the body. There is no evidence, for example, for the belief that nursing infants can become intoxicated from alcohol ingested by the mother. Also, the amount and quality of the milk are undisturbed by the taking of alcohol in moderation by the nursing mother. Traces of alcohol are found in the bile, but are apparently reabsorbed by the intestine.

Concentration of Alcohol in the Blood and Its Relation to Alcoholic Intoxication. Within five minutes after its ingestion, alcohol can be detected in appreciable amounts in the blood. It is carried especially in the plasma which is said to contain twice as much as the corpuscles. Inasmuch as alcohol is absorbed rapidly and oxidized slowly, it accumulates in the blood and tissues. After a single administration, the highest blood level is reached between the first and second hour and from then on it falls slowly, depending on the rate of oxidation, the degree of excretion, the amount remaining to be absorbed in the intestinal tract, and the presence or absence of tolerance.

The curve of blood alcohol concentration of the abstainer differs from that of the habitual drinker. In the former, the blood concentration remains high for several hours, whereas in the habitué the peak level is reached more quickly and is lower, and the curve descends rapidly after two hours. The character of the curve also depends on the concentration of ingested alcohol. Miles (1924) gave 27.5 grams of alcohol in two dilutions, in one case diluted with water to 1000 cc and in the other to 100 cc. In the first instance, the concentration in the venous blood was lower and slight symptoms or none were noted, whereas with the stronger drink higher levels and definite symptoms were observed. These results are summarized in Table 3.

TABLE 3

ALCOHOL CONTENT OF THE BLOOD AND URINE AFTER TAKING 27.5 GRAMS IN DIFFERENT SOLUTIONS *

(Miles, 1924.)

	ALCOHOL IN MGM PER CC AFTER 27.5 GRAMS IN 1000 CC				ALCOHOL IN MGM PER CC AFTER 27.5 GRAMS IN 100 CC			
Time (minutes)	20	40	70	120	20	40	70	120
Blood conc. **	.18	.24	.31	.31	.29	.43	.44	.37
Urine conc.	.16	.38	.48	.43	.26	.54	.63	.50

* Average of nine subjects.
** Blood samples taken two minutes after urine samples.

The blood level of alcohol which indicates intoxication or drunkenness is a matter of dispute. Generally, however, it is agreed that an alcohol concentration of 0.20 per cent (200 mgm per cent) either in the blood or urine is associated with mild to moderate intoxication. This has been called the "crucial concentration." In some persons, of course, this level does not indicate drunkenness, and it must be viewed merely as an average. In the same sense, a blood level of 0.25 per cent usually signifies moderate to marked intoxication. Over 90 per cent of persons with concentrations of blood alcohol of 0.30 per cent are obviously intoxicated.

Jetter (1938) studied 1150 cases hospitalized with preadmission diagnoses of acute alcoholism. In 1000 of these cases, the blood alcohol was determined and in 80 per cent ranged between 0.15 and 0.30 per cent. In 70 per cent of the 381 urine examinations, the concentration of alcohol varied from 0.20 to 0.35 per cent. The incidence of clinical intoxication found at different levels of blood alcohol is shown in Table 4.

TABLE 4

RELATIONSHIP BETWEEN INCIDENCE OF CLINICAL INTOXICATION AND LEVELS OF BLOOD ALCOHOL

(Jetter, 1938).

Blood Alcohol Concentration	0.05 %	0.10 %	0.15 %	0.20 %	0.25 %	0.30 %	0.35 %	0.40 %	0.45 %	0.50 %
Total Number of Cases	38	87	132	330	176	141	74	15	5	2
Number of Cases Intoxicated	4	16	61	276	158	133	71	14	5	2
Percentage of Cases Intoxicated	10.5	18.4	47.0	83.6	90.0	95.1	96.0	93.3	100	100

A blood alcohol value of 0.40 per cent always indicates advanced drunkenness. The fatal concentration lies between 0.50 and 0.80 per cent. Blood concentrations of alcohol below 0.20 per cent are often associated with unequivocal clinical evidences of intoxication. For example, with values around 0.06 per cent most people manifest definitely decreased competence; with levels of 0.10 per cent, about one-quarter of a group of individuals would be classified as intoxicated. As this level rises to 0.15 per cent, one-half would be considered clinically intoxicated. Inasmuch as expired air or urine may be more easily obtained than blood from an intoxicated person, the level usually set in medico-legal work for drunkenness is a urinary alcohol level of 0.20 per cent or a concentration of alcohol in exhaled air of 1.0 mgm per liter.

The amount of alcohol which must be ingested to cause given blood concentrations of alcohol varies from person to person and depends on many factors. In general, it may be assumed that for every 0.01 per cent of alcohol in the blood, from five to 10 cc of alcohol were ingested. On the basis of the latter figure, this is the equivalent of about 200 cc of beer (4.5 per cent alcohol by volume) or 25 cc of whisky. Also on this basis, drunkenness would usually be produced by 150 cc of alcohol, one pint of whisky or about seven average bottles of beer. When six to eight cc of alcohol per kg of body weight are rapidly absorbed, death usually occurs. This holds true for nearly all species of mammals. The quantitative differences in the effects of gin, whisky and beer on the blood alcohol levels of normal persons and the influence of the time of ingestion in relation to meals have been analyzed by Haggard and associates (1938).

In the following table are given the symptoms which ordinarily appear at different levels of ascending concentrations of blood alcohol in persons with ordinary sensitivity, as compiled by Miles (1932). It is of interest that for equal concentrations of alcohol in the blood, the effects are greater when the concentration is rising than when it is falling.

A SCALE OF TOXIC SYMPTOMS

(Miles, 1932)

Per cent alcohol in blood	Subjective state and observable changes in behavior under conditions of heavy social drinking.
0.010	Clearing of the head. Freer breathing through nasal passages. Mild tingling of mucous membranes of the mouth and throat.
0.020	Slight fullness and mild throbbing at back of head. Touch of dizziness. Sense of warmth and general physical well-being. Small bodily aches and fatigue relieved. Not fretful about the weather nor worried concerning personal appearance. Quite willing to talk with associates. Feeling tone of pleasantness.

0.030	Mild euphoria, "everything is all right," "very glad I came," "we will always be friends," "sure I will loan you some money," "it isn't time to go home yet!" No sense of worry. Feelings of playing a very superior game. Time passes quickly.
0.040	Lots of energy for the things he wants to do. Talks much and rather loudly. Hands tremble slightly, reaching and other movements a bit clumsy; laughs loudly at minor jokes; unembarrassed by mishaps, "you don't think I'm drunk do you, why I haven't taken anything yet." Makes glib or flippant remarks. Memories appear rich and vivid.
0.050	Sitting on top of the world, "a free human being," normal inhibitions practically cut off, takes personal and social liberties of all sorts as impulse prompts. Is long-winded and enlarges on his past exploits. "Can lick anybody in the country," but has observable difficulty in lighting a match. Marked blunting of self-criticism.
0.070	Feelings of remoteness. Odd sensations on rubbing the hands together, or on touching the face. Rapid strong pulse and breathing. Amused at his own clumsiness or rather at what he takes to be the perversity of things about him. Asks others to do things for him. Upsets chair on rising.
0.100	Staggers very perceptibly. Talks to himself. Has difficulty in finding and putting on his overcoat. Fumbles long with the keys in unlocking and starting his car. Feels drowsy, sings loudly, complains that others don't keep on their side of the road.
0.200	Needs help to walk or undress. Easily angered. Shouts, groans, and weeps by turns. Is nauseated and has poor control of urination. Cannot recall with whom he spent the evening.
0.300	In a stuporous condition, very heavy breathing, sleeping and vomiting by turns. No comprehension of language. Strikes wildly at the person who tries to aid him.
0.400	Deep anesthesia, may be fatal.

Tolerance to Alcohol. The repeated use of alcohol results in the development of tolerance, and larger doses must then be taken in order to procure characteristic effects. This tolerance nevertheless is not as marked as for morphine or nicotine. The alcoholic addict still has his upper limit of tolerance and this is usually only two to four times the amount of alcohol that can be taken by the occasional drinker.

The mechanism of tolerance is not clearly understood. Some claim that it is not a true tissue tolerance but rather that it is due to a more rapid rate of oxidation of alcohol in the addicted person. Others believe that retarded absorption is the cause. The work of Newman and Lehman (1938) on dogs and rats indicates that a real tissue tolerance for alcohol develops in habituated animals and that drunkenness appears only when a higher blood level of alcohol is reached than in the controls. They also showed that this acquired tolerance was not due to a decrease in brain permeability to alcohol and that the cells of the central nervous system acquire the ability to function more effectively at a given concentration of alcohol than before habituation occurred. Should this prove true for man, our ideas concerning the concentration of alcohol in the tissues as an index to intoxication would need to be altered. At present, those who disagree with the cellular tolerance theory claim that the chronic drinker becomes intoxicated when his tissue alcohol reaches the same level that produces intoxication in the abstainer, regardless of the actual amount of alcohol ingested. Finally, there is the belief that more alcohol is excreted by the tolerant individual.

Cross-tolerance to the closely allied hydrocarbon anesthetics is also exhibited by alcoholics. For example, it is difficult to anesthetize chronic alcoholics with chloroform, ether, or avertin.

Addiction to alcohol also occurs. However, an individual may be tolerant to alcohol and yet not manifest serious or pathognomonic withdrawal symptoms. In this respect, tolerance to alcohol differs from that to morphine in that the latter is rarely seen without accompanying addiction.

Alcohol as a Food. The combustion of alcohol begins within five or ten minutes after it is swallowed. Hence alcohol is utilized more rapidly than most foods. The energy released per gram of alcohol is approximately seven calories. This energy is available for body work. Alcohol spares carbohydrates and fats and increases glycogen and fat deposition because it cannot be stored in the body or utilized in tissue formation and can only be burned for its energy content. When the diet is deficient in carbohydrate, alcohol can spare protein but not quite as efficiently as can carbohydrate. Alcoholic beverages often contain other foodstuffs. For example, beer contains about 500 calories per quart, half of which are furnished by albuminous and carbohydrate substances.

Considerable controversy exists concerning the classification of alcohol as a food (Emerson, 1932). Alcohol differs from ordinary foods in several distinct ways. It can only be burned and cannot enter into the building of tissue. It is oxidized at a constant rate regardless of supply. Alcoholic beverages often contain no vitamins or accessory food factors, and alcoholic addicts are subject to vitamin deficiency (page 1249). Alcohol has definite pharmacological and toxicological properties not possessed by foods. Finally, taken over a long period of time, alcohol may cause severe organic and mental ailments.

Metabolic Actions. Depression and sleep which follow ingestion of large amounts of alcohol may lower the *energy production* of the body. The reverse is true during the excitement stage of alcoholic intoxication. *Nitrogen metabolism* is undisturbed by alcohol, with the exception of purine metabolism. *Uric acid elimination* is said to be increased, but the mechanism is unknown. The etiologic relation of alcohol to *gout* is not clear. Beer, a chief offender, contains purine substances. In the fully developed case of gout, alcohol appears to precipitate acute attacks but clinical reports differ in this regard.

Resistance to Disease and Infection. A very large amount of clinical and experimental work has failed to indicate that alcohol in therapeutic or moderate amounts has any *direct* effect on man's susceptibility or resistance to disease or infection. Alcohol neither increases susceptibility to tuberculosis, pneumonia or any other disease, nor does it offer any protection. Alcohol may interfere indirectly with the defensive mechanisms, but this is usually by impairment of general health. Thus, an alcoholic addict may stand less chance of recovery from disease. Rosenthal (1930) found that although moderate doses of alcohol in dogs caused only slight impairment of liver function, nevertheless the organ was more prone to damage by hepatotoxic agents. For example, chloroform given to these dogs following recovery from the alcohol caused the death of many of them. When the same amount of chloroform was given before the alcohol, no such lethal outcome was noted. The reader interested in this problem is referred to the discussion by Langmead and Hunt (1932).

Heredity and Longevity. The bulk of animal experiments appears to indicate that the prolonged daily feeding of moderate amounts of alcohol does not interfere with normal growth, maturation, or ability to reproduce. Whether larger doses cause lessened fertility, higher prenatal or early postnatal mortality, and impairment of the offspring is difficult to decide. Davenport (1932) concludes, "There is much evidence that generations of alcoholism in man have produced gametes relatively resistant to alcohol; so that diminished fertility of alcoholics and defective offspring of alcoholics are, at least, not the common result." Stockard (1932) concludes from his animal experimentation, "With full appreciation of all the difficulties in transferring the results obtained from the study of one animal kind to another, we may assume from the experiments on the effects of alcohol in development and inheritance that it is highly improbable that the quality of human stock has been at all injured or adversely modified by the long use of alcohol." The statements regarding the inheritance of proclivity for alcohol, and the high incidence of mental defects, insanity or epilepsy in offspring of alcoholic parents must certainly be critically analyzed. Most of these conclusions are from statistical analyses and the latter are notoriously susceptible to manipulation by biased persons. The children of thousands of drunkards were found the equal of other children. While it is true that children may inherit the defects (insanity, mental deficiency, etc.) which caused alcoholism in the parent, they do not inherit the alcoholism itself.

Actuarial statistics show that heavy drinkers have a shorter span of existence than do abstainers. Whether the prolonged use of moderate amounts of alcohol similarly shortens life, however, is an entirely different problem. Animal experiments tend to show the innocuousness of small amounts in regard to length of life. Pearl (1926) made an extensive study of over 5000 persons in Baltimore whose family records extended over several generations. His conclusions indicate that moderate drinking of alcohol does not shorten life but may actually enhance life expectancy above that of abstainers. Heavy drinkers showed a decreased life expectancy. Despite the numerous objections raised to Pearl's work, it accords with the general trend of clinical opinion that moderate amounts of alcohol may be taken daily with no demonstrable injurious effect. This amount is certainly less than that which causes clinical intoxication. The question is one of the wise use of alcohol as compared to its abuse.

In closing his book on the longevity problem, Pearl (1926) quotes the following humorous pronouncement of Henry Arthur Jones (*The English Review,* December, 1924): "With respect to alcoholic disease, as with other diseases, the chief thing is to get oneself born with an immunity to it. I took this precaution against alcohol, and thereby have been able to enjoy a bottle of wine a day without ever getting drunk, without ever approaching drunkenness, without ever wishing to take more than was good for me. Such are the advantages of belonging to God's elect, as the apostle affectionately calls us. . . . As one born with a joyous capacity for taking a moderate, harmless quantity of wine, I strenuously protest being degraded into equality with C_3 degenerates to whom alcohol is poison. Of all the devastating applications of the false and abominable doctrine of equality, this is one of the most intolerable. Why should a poor but healthy labouring man, whose rich brawny thews and vigorous stomach righteously demand a draught of refreshing ale, be condemned to meagre and gloomy equality with the rich valetudinarian, to whose queasy digestion a mere sip of alcohol is veritable poison? Away with this damnable doctrine of equality when it tells so hardly upon the working man!"

Pathological Effects. This subject can be only briefly reviewed here. Definite histological changes in tissues occur only with the prolonged use of large amounts of alcohol. Even in these cases, it cannot be said with certainty that the alterations are due to the alcohol, because identical changes may occur in abstainers. The nervous system and the digestive system are most markedly affected. In the former, structural changes due to alcohol can rarely be recognized. Polyneuritis and alcoholic pellagra are known not to be due to alcohol and can be cured by proper therapy without removing alcohol from the diet (page 1249). Chronic gastritis and achlorhydria may be seen in heavy drinkers. The so-called alcoholic cirrhosis of the liver is encountered in those who drink spiritous liquors rather than light beverages, but the problem of etiology is unsettled. Animal experiments with alcohol alone are negative as regards cirrhosis and reports on human autopsy series vary. It is certain that a similar cirrhosis can be seen in abstainers. The possible etiological rôle of the copper present in certain alcoholic drinks has been emphasized by some, especially Mallory (page 1119). The relation of alcohol to cirrhosis of the liver has been reviewed by Connor (1940). The kidneys are not greatly affected by alcohol. There is no evidence that alcohol is directly responsible for serious organic heart disease. The studies of White and Sharker (1934) indicate that the use of alcohol bears no relation to the incidence of angina pectoris. Many toxic effects previously attributed to alcohol may be due to impurities in the beverages consumed. The use of methyl alcohol as an adulterant provides a familiar example. The possibility that higher alcohols and aldehydes of "raw" whiskies may cause damage must not be overlooked. This subject has been reviewed by Martland (1932).

Preparations. Alcohol, whisky and brandy are official preparations. *Alcohol* (Ethyl Alcohol), U.S.P., B.P., contains not less than 92.3 per cent by weight (94.9 per cent by volume) of C_2H_5OH. Its appearance and chemical properties need not be described here. *Dehydrated Alcohol,* ("Absolute Alcohol"), U.S.P., B.P., contains not less than 99 per cent by weight of C_2H_5OH. *Diluted Alcohol,* U.S.P., is a mixture of alcohol and water, containing not less than 48.4 per cent and not more than 49.5 per cent by volume of C_2H_5OH. The B.P. includes a series of diluted alcohols ranging from 20 to 90 per cent of C_2H_5OH by volume. *Whisky* (Spiritus Frumenti), U.S.P., is an alcoholic liquid obtained by the distillation of the fermented mash of wholly or partly malted cereal grains, and contains not less than 47 per cent and not more than 53 per cent by volume of C_2H_5OH. It must have been stored in charred wood containers for a period of not less than four years. It is a pale to deep amber-colored fluid with a characteristic odor and taste. *Brandy* (Spiritus Vini Vitis), U.S.P., is an alcoholic liquid obtained by the distillation of the fermented juice of sound ripe grapes, and contains not less than 48 per cent and not more than 54 per cent by volume of C_2H_5OH. It must have been stored in wood containers for a period of not less than four years. It is a pale amber-colored fluid with a characteristic odor and taste.

In addition to official preparations of alcohol, numerous alcoholic beverages are commercially available throughout the world, including various types of gin, wine, liqueurs, ale and beer. Alcohol is also a main constituent of several classes of vehicles (page 1321).

Therapeutic Uses of Alcohol. Alcohol and alcoholic beverages are used widely by the laity for a large number of ailments and the proper delimitation of its legitimate uses in medicine is sometimes difficult.

External. Alcohol is an excellent *solvent* for many drugs, and is frequently employed in *medicinal mixtures* as a vehicle. Alcohol is a solvent for the *toxicodendrol* causing ivy poisoning; early and thorough washing of the affected parts with alcohol may abort or lessen the severity of this dermatitis. Alcohol (25 per cent) *cools* the skin when allowed to evaporate and alcohol sponges are therefore used in fevers. It is also a *rubefacient* and is included in liniments. Alcohol (50 per cent) is employed in bed-ridden patients in order to prevent *decubitus ulcers.* It is also used to *decrease sweating* and is an ingredient of many anhidrotic and astringent lotions. As an *antiseptic,* alcohol (70 per cent) is employed chiefly on the skin but also for instruments. In *phenol skin burns,* alcohol should be used immediately as a wash if castor oil is not available as a solvent. It is not to be employed as a lavage when phenol has been swallowed (page 829).

Injection for Relief of Pain. Strong alcohol may be injected around nerves or ganglia for the relief of pain. In the treatment of *angina pectoris,* injection of alcohol (two cc of 95 per cent) into stellate and upper dorsal sympathetic ganglia is often preferable to and certainly much safer than ganglionectomy. In *trigeminal neuralgia,* injection of alcohol into the affected nerve at its exit from the skull will often relieve pain for many months. In the pain produced by inoperable *carcinoma, tuberculous laryngitis,* etc., alcohol injection of the regional nerves is a valuable procedure. The agonizing itching of *pruritus ani* may be relieved by the subcutaneous or intracutaneous injection of alcohol in the afflicted area. Epidural injection of alcohol in the sacral region may be utilized to relieve the intractable pain of *pelvic carcinoma* before chordotomy is resorted to (Saltzstein, 1938).

Alimentary Tract. Alcoholic beverages, if enjoyed by the patient, may be given before meals as a *carminative* to improve appetite and digestion. This practice is especially useful in convalescent and debilitated or elderly people. In flatulence and colic, alcohol may give relief. The reflex stimulation arising from alcohol in the mouth, throat and stomach is utilized to treat *fainting.*

Systemic Uses. Alcohol acts as a *hypnotic* and *antipyretic* and is widely employed for these purposes by the laity. Alcoholic beverages, such as milk punches and eggnogs, are sometimes valuable for convalescents as rapidly assimilable sources of *energy.* Whisky or champagne may be the only food tolerated by febrile, restless patients. A hot toddy before bedtime is an old-fashioned remedy for *insomnia.* It may often produce results where other agents fail, due perhaps to the feeling of well-being which mild cortical depression and freedom from worry produce. Alcohol is used to cause vasodilatation in persons with *peripheral vascular* *disease* and its administration in *coronary artery disease* to lessen the frequency and severity of anginal attacks is quite valid. Alcohol is one of the few effective coronary vasodilators and is considered the best drug for angina pectoris. "Whisky and soda" is perhaps the alcoholic drink of choice for cardiac patients. Beer and cold drinks should be avoided.

The use of alcohol to check a *"cold"* deserves special mention. For generations, alcoholic beverages have been used to abort the development of impending "head colds," especially after chilling by exposure to inclement weather. Without contending that such a practice is effective or that it can stay the self-limited course of the common cold, it should be stated that alcohol has certain actions which, though not indispensable, may be of benefit. The vasodilatation resulting from alcohol aids in reestablishing the circulation in chilled cutaneous and mucosal surfaces. Also, if alcohol makes the patient drowsy or sleepy so that he stays in bed whereas otherwise he would be ambulatory, it may serve a useful purpose. Hamburger (1936) has for years humorously advised the following therapy, culled from an old English book, to be instituted at the first inkling of a cold, namely, to hang one's hat on the bedpost, drink from a bottle of good whisky until two hats appear, and then get into bed and stay there.

Contraindications. In hepatic and renal disease, alcohol should probably not be used. Ulceration of the gastro-intestinal tract or hyperacidity giving rise to digestive complaints is also a contraindication. Alcohol should not be taken by epileptics. In acute infections of the urinary tract, alcoholic beverages are to be avoided. Alcohol should be forbidden to patients who may easily become addicted to it. The use of alcohol in the presence of any particular disease is a matter which the physician must decide in each individual case.

Acute Alcoholic Intoxication

The characteristic signs and symptoms of acute alcoholic intoxication are well known. Nevertheless the mistaken diagnosis of drunkenness is often made in patients who appear inebriated but have not ingested alcohol. Great care should be taken to make certain that the patient's symptoms are due to alcohol. For example, approximately 10 per cent of 1159 consecutive cases with the preadmission diagnosis of acute alcoholism were found not to have ingested alcohol. Barbital, paraldehyde, cardiovascular accidents, schizophrenia and fractured skull, in the order named, were the most common causes for the erroneous diagnosis (Jetter, 1938). The odor of the breath is a notoriously unreliable guide and may often be seriously misleading. For medicolegal purposes, the concentration of alcohol in the blood, urine, saliva or exhaled air should be determined.

In severe intoxication, alcohol manifests an anesthetic action. The patient is stuporous or comatose. The skin is cold and clammy, the body temperature low, the respirations slow and noisy, the pupils normal or dilated, and the heart rate accelerated. If this condition persists for eight or ten hours, hypostatic pneumonia or increased intracranial pressure may intervene. Death is rare unless unconsciousness continues for many hours or trauma or infection complicates the case. Recovery is jeopardized if deep coma persists for over 12 hours.

Treatment. The patient should be kept warm. The stomach may be lavaged through a tube, but care must be taken to prevent aspiration of the return flow. Apomorphine should not be employed as an emetic because in itself it is depressant, after brief stimulation, and thus adds to the depression due to the alcohol. Caffeine is an effective antagonist to alcohol. It can be given rectally as strong black coffee, or caffeine with sodium benzoate (0.5 gram) may be injected intramuscularly. Ephedrine and other stimulants may also be employed. The value of metrazol has been emphasized by the report of Orenstein and coworkers (1939). If the respiration is greatly depressed, inhalation of carbon dioxide and oxygen may be necessary. Increased intracranial pressure due to cerebral edema is treated by the usual medical measures outlined under methyl alcohol poisoning. The promising results obtained with combined glucose and insulin therapy by Goldfarb, Bowman and Parker (1939) in acute alcoholic intoxication have already been presented in detail. In other respects, treatment does not differ greatly from that of toxic depression caused by anesthetics or hypnotics, and reference should be made to the therapy of barbiturate and morphine poisoning. The posture of the patient should be changed frequently in order to prevent hypostatic pulmonary complications. Postalcoholic headache and gastritis also require attention.

Chronic Alcoholism

The effects of the chronic use of immoderate amounts of alcohol on the organs of the body, length of life, fertility, and character of the progeny have already been discussed. The signs and symptoms of chronic alcoholism vary and may include those of gastro-enteritis (anorexia, nausea, vomiting and diarrhea); dilatation of skin capillaries, especially those of the face; loss of weight, malnutrition and cachexia; alteration in personality, delirium tremens, mental and moral deterioration; alcoholic cirrhosis, pellagra, polyneuritis, optic atrophy, and coincident serious organic disorders due to lowered vitality and resistance.

Treatment. Alcoholic patients as a rule are either hereditary defectives (often mentally deficient) or psychopathic personalities. Taking away the whisky bottle does not cure a drunkard. Wide personality and environmental readjustments are usually necessary. The major points to be followed in treatment are as follows: (1) Hospitalization in special nursing homes or retreats is often essential. (2) Adequate medical supervision and nursing care are paramount and should be undertaken only by those trained for this work. (3) Gradual withdrawal of alcohol is the safest procedure and lessens the danger of delirium tremens. (4) Proper sedation is an important part of symptomatic therapy. Paraldehyde and chloral hydrate are particularly helpful. Belladonna alkaloids are often used, as in the treatment of morphine addiction. (5) Psychotherapy, maintenance of nutrition and general hygiene, and firm but sympathetic management are essential.

Relapses are frequent in addicts to alcohol, although the prospects of cure are more promising than with morphine or cocaine addicts. A special problem arises in chronic drinkers who develop an *acute alcoholic psychosis*. This may last for days or even months and is characterized by auditory hallucinations, delusions of persecution, and suicidal or homicidal tendencies. The patient with an acute alcoholic psychosis should be institutionalized and treated as an acutely insane person.

DELIRIUM TREMENS

Delirium tremens is a syndrome seen in chronic alcoholism and confined to heavy drinkers. It may occur without apparent cause but usually starts after a particularly heavy bout of drinking, after trauma or fracture, during the course of an acute infection, or upon attempts to withdraw the alcohol. It represents an acute psychotic episode.

Symptoms. Prodromes of restlessness and insomnia may precede the onset of delirium tremens by several days. The two characteristic symptoms are tremors of the entire body and an acute delirium. From these features, the disorder derives its name. The delirium consists chiefly of visual and not auditory hallucinations, as in acute alcoholic insanity. These hallucinations are very real and terrifying. In fact, they are so realistic, that after recovery it is difficult to convince the individual that his experiences were illusory. The sufferer is entirely disoriented as to time and place but not as to person.

Other symptoms and signs are referable to the marked exhaustion which results from the constant movement, and the dehydration and malnutrition from the lack of water and food. The stage of excitement may continue for several days, and the patient may not eat, drink or sleep. Also, cerebral edema is not uncommon, and choked discs, headache, vomiting and coma may follow. Death can easily occur from exhaustion or intercurrent infection, and usually results from heart failure or hypostatic pneumonia. The mortality rate is high. If recovery occurs, it is gradual and delirium may be followed by a period of stupor.

Treatment. Successful treatment consists in giving encouragement and reassurance, and competent and sympathetic nursing care. It is imperative to quiet the patient and, if at all possible, to put him to sleep. If sleep lasts for seven or eight hours, the outlook is hopeful. Paraldehyde, given orally or rectally in doses of from 10 to 15 cc two or three times daily, is one of the best hypnotic agents in delirium tremens. Chloral hydrate in doses of two or three grams may also be used. Morphine should not be given because it increases intracranial pressure. If the patient is extremely restless and the usual measures to produce sleep have failed, one of the shorter-acting barbiturates may be given intravenously in the smallest amount necessary to give the desired result. Sodium amytal or pentobarbital may be used and is especially indicated if the patient is unmanageable. Given early, this may prove to be the best therapy. Once the patient is asleep, he should not be disturbed for any reason.

The patient should be kept in bed and warm. Special provision is made to insure an adequate food intake. The diet should be liquid or soft, and high in carbohydrate, calories and vitamins. If acidosis is present, this must be combated by the usual measures. Alcohol should be abruptly and completely withdrawn, despite the older practice of giving not only alcohol but also making certain that it was the same kind of beverage to which the patient was accustomed.

If there is evidence of increased intracranial pressure due to cerebral edema, a hypertonic solution of dextrose should be injected intravenously. Spinal fluid drainage, however, is probably to be preferred and some employ this measure routinely in all cases of delirium tremens (*see* Cline and Coleman, 1936). As much fluid is drained off as is readily removable, but the drainage should be done slowly. Other workers, however, believe that patients with delirium tremens should routinely receive from 3000 to 4000 cc of fluid daily unless fluids are specifically contraindicated. Thus Bowman, Wortis and Keiser (1937), from an extensive experience, advise that attention be given to supplying ample fluid and electrolyte and that lumbar puncture be done for diagnosis only and not for therapy. A similar opinion is advanced by Thomas, Semrad and Schwab (1939) who, in a carefully controlled study of the effects of dehydrating measures in delirium tremens, found that somewhat better results were obtained by giving ample fluids than by spinal drainage and fluid restriction, but that the difference was not striking. Likewise, Piker (1939) concluded that fluids should be neither restricted nor forced. His study consisted of 300 consecutive cases of delirium tremens divided into two equal groups, half of the patients receiving less than 1000 cc of fluids daily and the remainder receiving from 3000 to 4000 cc daily, treatment otherwise being similar. The number of deaths and the average duration of the illness were the same for the two groups. Many patients with delirium tremens are dehydrated when first observed and, by actual measurement, do not have increased intracranial pressure. To restrict fluids in these individuals may do harm. Nearly all observers, regardless of their views on the question of fluids, lay greatest emphasis on the importance of food and sleep.

Supportive treatment is supplied as needed. The practice of routine digitalization has no rational basis in the therapy of delirium tremens. Subdigitalization may be carried out when patients appear to be bad cardiac risks, and digitalization completed if congestive heart failure appears. It has been suggested that the intravenous administration of thiamine facilitates recovery from delirium tremens (Kiene and coworkers, 1940) but this point requires substantiation. There is also an encephalopathic syndrome which occurs in chronic alcoholic addicts which may be due to a deficiency of nicotinic acid (page 1258).

METHYL ALCOHOL

Methyl alcohol (CH_3OH) is known also as *wood alcohol* and *Columbian spirit.* It is the simplest of the alcohols.

Uses. Methyl alcohol is widely employed industrially as a solvent and occasionally as an adulterant in ethyl alcohol. It has no medicinal uses and is purely of toxicological interest. Poisoning can occur from its ingestion or from industrial exposure. During prohibition years in the United States, serious or fatal poisoning from methyl alcohol was not uncommon.

Fate in the Body. Methyl alcohol is longer-acting and more slowly oxidized in the body than ethyl alcohol. One-third of it still remains in the tissues forty-eight hours after ingestion. Within this two day period, approximately 40 per cent of the methyl alcohol is oxidized, 20 per cent is excreted unaltered through the lungs and three per cent is excreted as such in the urine. It is oxidized to formic acid ($HCOOH$) which is also excreted in the urine.

Methyl Alcohol Poisoning. Poisoning due to methyl alcohol results from a combination of the following factors: (1) central nervous system depression similar to that produced by ethyl alcohol; (2) acidosis due to the production of formic acid; (3) cerebral edema; (4) a specific toxicity of methyl alcohol for the optic nerve.

Symptoms. Inebriation is a prominent symptom of methyl alcohol intoxication. Violent gastric pains and vomiting are quite common and are due to the irritant action of methyl alcohol. Vision is disturbed quite early and the pupils are dilated and usually do not react to light. Dyspnea and cyanosis are prominent and acidosis must often be combated. Direct cardiac depression occurs and is due to both methyl alcohol and formic acid. Marked and protracted delirium is not unusual. Respiratory and circulatory failure, collapse and coma then ensue. Death may be delayed for several days following the onset of coma. If death does not occur, recovery is quite slow. This prolonged period of intoxication is in sharp contrast to that produced by ethyl alcohol. If the patient recovers, he may be totally blind. Once damaged, the vision usually shows no great improvement. Methyl alcohol is apparently toxic to both the optic nerve and retinal cells. Susceptibility to optic damage varies greatly. It may result from as little as 15 cc of methyl alcohol.

Treatment. The stomach should be washed and a four per cent solution of sodium bicarbonate may be left in the stomach to aid in the treatment of acidosis and to lessen gastric irritation. If abdominal pain is severe, morphine should be used. For delirium, scopolamine hydrobromide, in 0.2 to 0.5 mgm dosage, may be given. The patient should be kept warm and nutrition maintained. Acidosis and shock should be treated in the manner outlined elsewhere. Cerebral edema, when present, is combated by hypertonic intravenous glucose or sucrose (50 to 100 cc of 50 per cent solution, repeated as needed), lumbar puncture with removal of 50 to 75 cc of spinal fluid, magnesium sulfate orally in 30 to 60 gram doses, and restriction of fluid intake. The remainder of the treatment is supportive and symptomatic. Caffeine, ephedrine, coramine, and artificial respiration may be necessary if respiratory failure occurs.

CHAPTER 9

HYPNOTICS AND SEDATIVES

I. THE BARBITURATES

The barbiturates comprise an important and valuable group of central nervous system depressants frequently prescribed by physicians and widely used by the laity. New barbiturates are constantly being introduced, usually under confusing trade names, and claims are often made that a particular compound is superior regarding potency, margin of safety or duration of action. At times it appears that the only goal in producing new barbiturates has been to obtain their exclusive sale by the manufacturer.

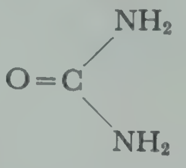
The proper selection and rational use of the barbiturates rest upon an intimate knowledge of their pharmacology and toxicology, as well as an acquaintance with the important variations in action and toxicity manifested by certain individual members. In this section, therefore, the barbiturates will be discussed as a group and important differences in the behavior of specific barbiturates will be mentioned as occasion arises. This is possible for the reason that many members of the group do not differ significantly from barbital or phenobarbital in their pharmacology or therapeutic uses. Indeed, the major variations occur in the duration of depressant action and in the suitability for use as an intravenous anesthetic.

The pertinent literature on the subject of the barbiturates has been reviewed by Lundy and Osterberg (1929) and by Tatum (1939).

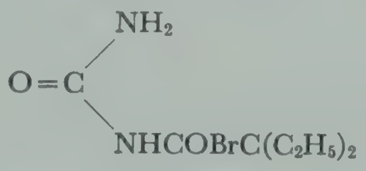
History. Barbital, the oldest barbiturate, was first introduced into medicine by Fischer and von Mering under the trade name of *veronal* in 1903. Barbital has survived many years of clinical trial, has long been official in the U.S.P., and is still one of the best hypnotics. The second oldest barbiturate is phenobarbital, introduced into therapeutics several years after barbital under the trade name of *luminal*. It too has proved its worth, and for many purposes deserves preference over certain newer barbiturates, the ultimate clinical value of which remains to be established. In the following years more than a score of barbiturates were synthesized and marketed for clinical use. The chief advantage of several of these drugs is their shorter duration of action as compared with barbital and phenobarbital. The latest advance has been the substitution in the barbituric acid molecule of sulfur for the oxygen on the urea carbon, and this has given rise to an entire homologous series of compounds with distinctive properties and special uses.

Chemistry. Barbituric acid is malonylurea, a combination of malonic acid and urea. Urea is not in itself a central depressant. Substitution products of urea, however, may have definite hypnotic power. This is true of the *ureides* which are formed from the combination of urea and organic acids.

Ureides fall into two groups, the *monoureides* and *diureides*. The monoureides are compounds in which only one of the amino groups of urea is condensed with a carboxyl group. An example of a sedative monoureide is *carbromal* (U.S.P.). Its formula and relation to urea are as follows:



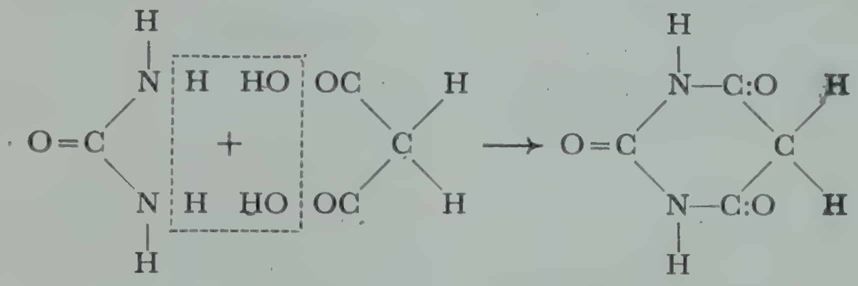
Urea



Carbromal

The monoureides are decomposed in the body to urea and are readily eliminated, their margin of safety thus being large. The clinical use of monoureides has given disappointing results due to the feeble depressant effects.

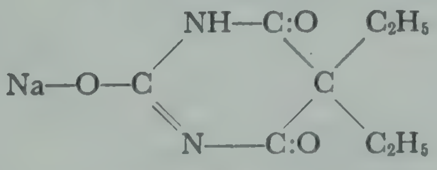
The diureides, which result from the combination of organic acid radicles with both amino groups of urea, are more powerful hypnotics. The main diureide from a pharmacological point of view is *barbituric acid,* the condensation product of urea and the dicarboxylic malonic acid, as shown in the following reaction:



Urea + Malonic acid Barbituric acid (Malonylurea)

The two hydrogens of barbituric acid which are indicated in bold-faced type in the foregoing formula are quite reactive and can be replaced by various radicles. Many series of chemical derivatives of barbituric acid have been prepared and are called *barbiturates* or *barbituric acid derivatives.* Barbital itself results from the replacement of the two **H's** by ethyl groups to form diethylbarbituric acid (diethylmalonylurea). If an ethyl group of barbital is replaced by a phenyl group, phenobarbital is obtained. Most of the barbiturates employed clinically have alkyl groups substituted in the barbituric acid nucleus; but other radicles can easily be inserted and two compounds (evipal and phanodorn) have a complex cyclic radicle replacing a reactive hydrogen (Table 5).

Despite the fact that barbituric acid derivatives do not contain a carboxyl group they have acidic properties due to the fact that the lactam form (—CO—NH—) is in equilibrium with the lactim form (—C(OH):N—), the hydrogen of which is readily dissociated, allowing formation of salts with alkalis. For example, the sodium salt of diethylbarbituric acid (sodium barbital) may be considered to have the following structural formula:



Sodium Barbital

Table 5
BARBITURATES AVAILABLE FOR CLINICAL USE

Barbiturate	Status	Chemical Name	Structural Formula	Average Adult Hypnotic Dose
				Grams
Alurate *	N.N.R.	Allylisopropylbarbituric acid	 $** R\begin{array}{l}\diagup CH_2CH{:}CH_2\\ \diagdown CH(CH_3)_2\end{array}$	0.065–0.13
Amytal *	N.N.R.	Isoamylethylbarbituric acid	 $R\begin{array}{l}\diagup CH_2CH_2CH(CH_3)_2\\ \diagdown C_2H_5\end{array}$	0.1–0.3
Barbital *	U.S.P. B.P.	Diethylbarbituric acid	 $R\begin{array}{l}\diagup C_2H_5\\ \diagdown C_2H_5\end{array}$	0.3–0.5

† Supplied commercially in Great Britain.

An entirely new series of barbiturates has been obtained by the substitution of sulfur for the oxygen on the urea carbon. The compounds which result from the condensation of thiourea and malonic acid are known as *thiobarbiturates*, the unique properties of which are described later.

In Table 5 are presented the chemical names and formulas of the official and N.N.R. compounds available in the United States, as well as the more commonly employed preparations not as yet accepted by the Council on Pharmacy and Chemistry. It will be observed that only barbital, phenobarbital and pentobarbital are official U.S.P. drugs. The proprietary barbiturate known as *nembutal* is chemically identical with U.S.P. pentobarbital sodium (*see* Report of the Council, 1937). The only N.N.R. (1940) thiobarbiturate is *pentothal,* the sulfur homologue of U.S.P. sodium pentobarbital. *Dial,* diallylbarbituric acid, is no longer included in the N.N.R. The ending "al" is common, with a few exceptions, to all of the barbiturates.

Relation Between Chemical Structure and Pharmacological Action. Several hundred barbiturates have been prepared but less than one hundred have been carefully studied for their pharmacological properties. From these studies certain general principles of chemical structure as related to pharmacological action are fairly well established, some of which may be briefly presented. Both of the reactive H's of barbituric acid must be replaced by alkyl or aryl groups in order to obtain compounds with hypnotic properties. An increase in the length of one or both alkyl side-chains results in enhanced potency and diminished duration of depression; but if the side-chains substituted for the reactive hydrogens of barbituric acid are too long (*i.e.,* over five or six carbon atoms), the hypnotic potency decreases and convulsive properties may appear. Alkyl groups attached to both of the *N* atoms also tend to yield convulsant compounds. In general, barbiturates with alkyl radicals are relatively stable in the body, while those with complex cyclic radicals, such as evipal, are unstable and readily destroyed. Derivatives of thiobarbituric acid are likewise rapidly decomposed in the body and therefore are short in duration of action. Compounds with branched side-chains are likely to manifest a brief duration of depressant effects and unsaturation in the side-chain tends to result in increased hypnotic activity. Isomers may exhibit quite different pharmacologic properties. For example, an anesthetic dose of amytal inhibits the cardiac action of the vagus whereas an equivalent amount of its isomer, pentobarbital, apparently lacks this effect. The substitution of a phenyl for an ethyl radical in barbital is the basis for the specific anticonvulsant property of phenobarbital in epilepsy. The fate of barbiturates in the body depends on their chemical structure. For example, barbital and phenobarbital are excreted in the urine, whereas amytal, pentobarbital, evipal and thiobarbiturates are largely destroyed in the body. It is thus evident that slight changes in chemical structure of the substituted groups in the barbituric acid nucleus or the replacement of the urea oxygen by sulfur affect significantly the action, fate and excretion of the resulting compounds.

Pharmacological Actions

The major action of the barbiturates and the one for which they are employed in medicine is central nervous system depression, essentially similar in character to that caused by the hydrocarbon anesthetics of the methane series.

Central Nervous System. All the numerous barbiturates have the same general type of depressant action on the cerebrospinal axis. They may be considered, at least from a clinical point of view, as differing mainly in the dose in which they are effective, in speed of onset of action, in duration of the hypnotic effects and in their usefulness for specific purposes. Any degree of depression from slight sedation to deep coma can be obtained with the barbiturates. The central depressant effects are therefore employed to produce calmness, to induce sleep, to depress the motor cortex and thus inhibit convulsions, and to cause partial or complete surgical anesthesia. The intensity of action obtained depends not only upon the particular barbiturate selected and the dose and route of administration employed, but also in large measure upon the reflex excitability of the patient's nervous system (page 49).

Hypnosis. The barbiturates are used more for the production of sleep than for any other purpose. With adequate oral doses of nearly any barbiturate, sleep occurs in from 20 to 60 minutes. The sleep is dreamless and, as a rule, refreshing. When the longer-acting barbiturates are employed there may be a "hangover" upon awakening.

Analgesia. The barbiturates differ sharply from both the opium alkaloids and analgesics, such as the salicylates, in that they lack the property of obtunding pain sense without loss of consciousness. The barbiturates are thus not analgesics and cannot be depended upon to produce sedation or sleep in the presence of pain. Indeed, if given alone under this circumstance, they are likely to induce delirium. Nevertheless, when they are combined with analgesic drugs such as the salicylates, they render the analgesia more effective. The reverse is not true, however, and in the absence of pain the analgesic drugs do not potentiate the hypnotic action of the barbiturates.

Anticonvulsant Action. In anesthetic doses, all of the barbiturates are capable of inhibiting convulsions, such as in strychnine poisoning, tetanus and status epilepticus. Phenobarbital, however, has a selective action on the *motor cortex* in epileptic patients when given in sedative doses, but this property is not shared by other members of the group. The specific corticomotor depression produced by phenobarbital has been experimentally demonstrated by several workers. Keller and Fulton (1931) found that this drug alone, of several barbiturates studied, completely abolished the electrical excitability of the motor cortex of monkeys when doses sufficient to cause full surgical anesthesia were employed. This was not true of anesthesia with dial, amytal, barbital, chloral hydrate or avertin. Merritt and Putnam (1938) noted that phenobarbital in sedative doses was much more effective than bromide in preventing convulsions in cats, electrically induced by stimulation of the motor cortex, and that other barbiturates did not increase the corticomotor threshold. This problem is further discussed under the use of phenobarbital in epilepsy.

Anesthesia. In sufficient doses, barbiturates can produce surgical anesthesia characterized by the same type of irregularly descending depression described for the volatile anesthetics. The actions of barbiturates on the brain and spinal cord, however, differ in many respects from those of the volatile agents. Some of these differences have been elucidated by experimental studies of the electrical responses (action potentials) of the brain under barbiturate anesthesia. For example, Derbyshire, Rempel, Forbes and Lambert (1936) found that marked electrical responses to sciatic nerve stimulation occurred in the cortex of cats under deep pentobarbital and dial (or avertin) anesthesia, but that these responses did not appear in deep ether anesthesia. It was concluded that afferent pathways leading to the cortex were blocked by deep ether anesthesia, but that barbiturate anesthesia, while inhibiting the spontaneous activity of the cortex, left it accessible to afferent stimuli. Forbes and Morison (1939), in a continuation of these experiments, have attempted more closely to localize the cerebral pathways involved. Their results, however, are somewhat at variance with those obtained by Bremer (1936, 1937), who believes that the barbiturates act selectively on internuncial cortical neurones rather than on afferent or motor paths, resulting in a functional "deafferentation" of the cerebral cortex. The cortical oscillograms obtained by Bremer after administration of a barbiturate resemble those reported for man in natural sleep.

Stages of Anesthesia After Intravenous Administration of Barbiturates. When the barbiturates are given intravenously for the production of anesthesia, the stages described in detail for the inhalation anesthetics are not readily delineated and indeed the induction phase may be impossible to detect. The patient appears to "fall asleep" quite suddenly during the course of a fairly rapid injection, sleep often interrupting the patient's conversation in the middle of a sentence. Only when the injection of a barbiturate is performed slowly can the stages of anesthesia be discerned. The induction period then resembles, in a general way, that noted with the inhalation anesthetics. The stage of surgical anesthesia is characterized by diminution or disappearance of superficial and deep reflexes, constricted pupils and fixed eyeballs, relaxation of the pharyngeal structures with falling backward of the tongue, shallow respiration and a fall in blood pressure, especially marked in patients with vascular hypertension. The signs vary with the amount of barbiturate administered and with the individual patient. When an overdose of drug is given, muscular flaccidity is marked, respirations are seriously depressed and the blood pressure falls early and rapidly to shock levels. *Recovery* is sometimes characterized by an initial period of restlessness, during which the patient may be irrational and hyperactive. Others experience a long period of sleep and immobility lasting for many hours and enhancing the danger of hypostatic pneumonia.

Locus of the Central Depressant Actions of Barbiturates. Despite the large amount of investigative work designed to elucidate the chief site of action of barbiturates on the cerebrospinal axis, many questions remain unanswered. It has been the custom of some pharmacologists to divide soporific drugs into two large groups, those acting mainly on the cortex and those affecting chiefly the diencephalic vegetative centers regulating sleep. The so-called cortical hypnotics were believed to be alcohol, paraldehyde, amylene hydrate, chloralose, bromide and certain of the substituted urea derivatives. Alleged diencephalic somnifacients were chloretone, urethane and a variety of barbiturates.

The *clinical evidence* for the belief that barbiturates have a selective site of action rests on the observations that sleep induced by barbiturates closely resembles physiological sleep, that patients with chronic encephalitis lethargica may be quite resistant to these drugs and that phenobarbital may markedly aggravate the rigidity in patients with parkinsonism.

Evidence from *chemical analyses* for barbiturate in the brain has been advanced to support the claim that these agents have a subcortical locus of action on vegetative and sleep centers. Keeser and Keeser (1927, *et seq.*), using both chemical and histological methods, reported a localized deposition of barbiturates in the thalamus and corpus striatum, none being noted in the cortex, pons, cerebellum or medulla. Other investigators, however, have not substantiated these findings. For example, Koppanyi and his associates (1934) failed to obtain chemical evidence for a selective distribution of barbiturates. Indeed, their data suggest that these drugs are found in approximately equal concentration throughout the brain. It is perhaps pertinent to recall that the bromides are distributed uniformly throughout the extracellular fluids of the body, and that selective depressant actions can therefore depend on special sensitivity of certain nerve cells to chemical substances rather than on concentration gradients at different sites.

However, it cannot be denied that the barbiturates may selectively depress certain functions mediated by subcortical centers. Leiter and Grinker (1934), for example, studying vasomotor and respiratory reactions to electrical stimulation of the hypothalamus in cats, found that the responses were more readily elicitable under ether than under dial anesthesia. Again, Masserman (1937) observed that amytal anesthesia markedly diminished or completely abolished the motor, sympathetic and emotional mimetic responses in cats incident to the faradic stimulation of the hypothalamus. The local intrahypothalamic injection of amytal, in contrast, caused neither sleep nor any apparent change in the sympathetic and emotional responses. These facts would indicate that amytal affects hypothalamic functions by other than a local action. Also, it is well known that the barbiturates antagonize the analeptic effects of picrotoxin, ephedrine and benzedrine, drugs known to act on the brain stem. Furthermore, by the use of thermocouple measurements of temperature changes in cortical and subcortical loci, Pick and coworkers (*see* Feitelberg, Pick and Warsberg, 1939) have demonstrated that barbiturates selectively depress the brain stem before the cortex.

Attention has also been centered on the finer mechanism of action of barbiturates on the *spinal cord.* Porter and Allamon (1936), for example, found that barbital, phenobarbital, amytal and evipal raise the threshold to sensory stimulation in the spinal cat to many times the original value, depending on the dose used, and that this action is antagonized by strychnine. The barbiturate-strychnine antagonism and its clinical applicability are more fully discussed on page 261. The similarity between the effect of low spinal transection and barbiturate anesthesia has been demonstrated by Beecher, McDonough and Forbes (1939). Both procedures greatly decrease after-discharge and curtail "long-circuiting" of sensory impulses in the cord, barbiturates differing from ether anesthesia in this respect.

Respiration. Soporific doses of the barbiturates are only slightly depressant to respiration. The decrease in respiratory exchange is mainly the result of sedation or sleep. Larger doses, however, are directly depressant to the medullary respiratory center and to a lesser degree to the sino-aortic chemoreceptors. Both the rate and depth of breathing are decreased and the rhythm may be irregular. In Figure

12 is shown the respiratory effect of a large somnifacient dose of sodium pentobarbital (0.28 gram) in a normal adult. Within three-quarters of an hour after the oral ingestion of the drug, the respiratory depth had decreased and the respiratory minute volume was lowered by 22 per cent.

Death from poisoning by barbiturates, as a rule, is due to respiratory failure. Marked depression of respiration is very apt to attend the intravenous injection of barbiturates for anesthesia and is one of the major dangers of this route of administration. In addition to direct depression of the respiratory center respiration may be embarrassed either by pulmonary edema or hypostatic pneumonia, the former usually appearing early in acute poisoning from over-medication with the short-acting drugs and the latter occurring late in the course of poisoning by the longer-acting barbiturates.

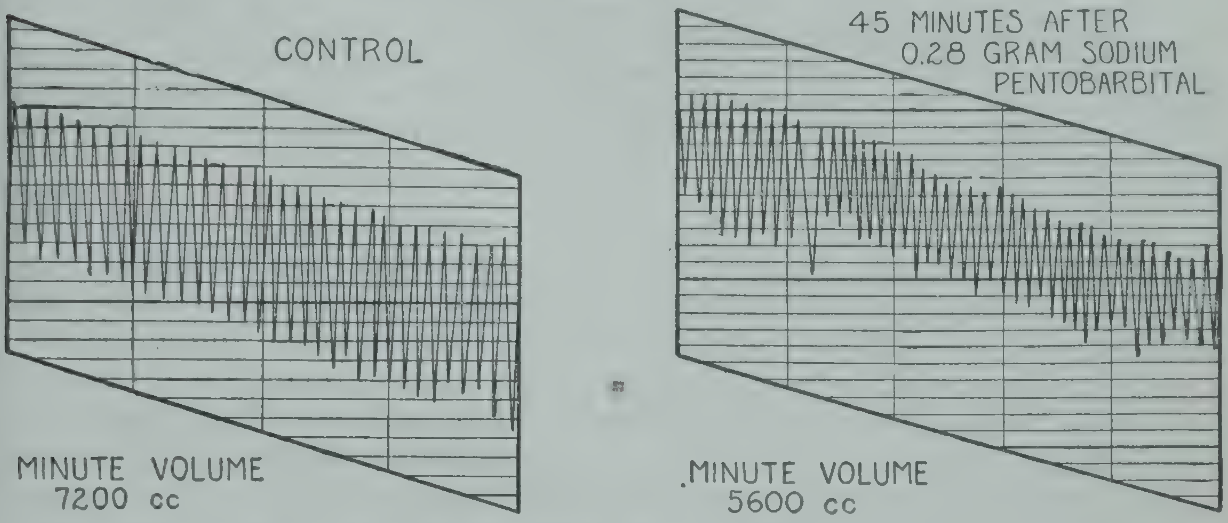

FIGURE 12. *The effect of a large hypnotic dose of sodium pentobarbital on the respiration.* Normal female, aged 62, 58 kg. Although the respiratory rate was not changed, the depth of respiration was significantly depressed, resulting in a 22 per cent decrease in respiratory minute volume. (Courtesy of Dr. Ralph M. Waters, Dept. of Anesthesia, University of Wisconsin.)

Cardiovascular System. Ordinary hypnotic doses of barbiturates have little effect on the cardiovascular system. The blood pressure and pulse rate may fall somewhat as a result of the quieting action or sleep produced by the medication. A sharp fall in blood pressure may result from the rapid intravenous injection of a relatively safe dose of a barbiturate, but the hypotension is transitory if the dose is not too large. Large doses of barbiturates depress the central vasomotor center and peripheral vasodilatation and hypotension follow. Barbiturates also can produce dilatation of the finer blood vessels by a direct effect on their musculature, and excessive concentrations may dilate and injure capillary beds to such an extent that shock ensues. The cerebral vessels tend to be dilated by the barbiturates, but the degree of vasodilatation varies with the individual members of the group. For example, Fulton and Keller (1932) observed that cerebral operations on chimpanzees were facilitated by the use of dial because of the vasoconstriction of cortical vessels produced, whereas amytal and pentobarbital were inclined to cause vasodilatation. Cardiovascular reflexes are diminished by anesthetic doses of the barbiturates and the carotid sinus mechanism is depressed.

The barbiturates, even when used intravenously for anesthesia, do not appear to be directly toxic to the myocardium, or seriously to alter cardiac rhythm or conduction.

In dogs and cats, the heart rate may be accelerated, the *T* wave transiently inverted, and a preexisting sinus arrhythmia decreased (Hafkesbring and MacCalmont, 1938). Experimentally in dogs, barbital appears to protect against ephedrine-induced arrhythmias (Meek and Seevers, 1934) and amytal against cardiac irregularities caused by cyclopropane anesthesia (Robbins and coworkers, 1939). Cardiac irregularities have been noted by Gruber and his associates (1938) to occur consistently in laboratory animals after the injection of thiobarbiturates. Betlach (1937), however, noted no significant electrocardiographic changes in dogs after pentothal, and Kohn and Lederer (1938) only occasionally observed cardiac irregularities from pentothal in a variety of animals. Also, Volpitto and Marangoni (1938), using pentothal and sodium thio-ethamyl as well as evipal, in 17 intravenous anesthesias in 12 patients, found no deviation from the normal in the electrocardiogram. Anesthesia with thiobarbiturate did not tend to sensitize the heart to epinephrine, although a tachycardia accompanies the anesthesia. The effects of thiobarbiturates on the cardiovascular system of man deserve considerably more study, although the available evidence indicates that the clinical use of these drugs causes no significant disturbances of cardiac rhythm.

Gastro-intestinal Tract. The barbiturates tend to decrease the general tonus of the intestinal musculature and the amplitude of rhythmic contractions as measured in experimental animals (Quigley and Phelps, 1934; Quigley, Barlow and Himmelsbach, 1934; Gruber and associates, 1936). Tournade and Joltrain (1936) found that, after evipal, stimulation of the vagus failed to produce the characteristic effects on the intestine. Whether the inhibition is due to a depression of the intrinsic ganglia or the enteric musculature is not known. Burstein (1939), however, has reported that after an initial phase of depression of intestinal movement following the intravenous injection of evipal, amytal, pentobarbital and thiobarbiturates in dogs with Thiry-Vella intestinal loops there occurred a more prolonged phase characterized by an increase both in tonus and contractions. The therapeutic effects of hypnotic doses of barbiturates in the relief of symptoms arising from the gastro-intestinal tract are attributable to central depressant actions.

Renal Effects. The barbiturates apparently have no direct effect on normal renal function. Urine formation, however, is influenced in at least two ways. Large doses of barbiturates have an antidiuretic effect and can inhibit water diuresis. Available evidence indicates that this action is probably a central one on the hypothalamic-pituitary system. It is not peculiar to barbiturates, however; it is also noted with other central depressants. The barbiturates can also affect urine secretion indirectly through the circulation. The hypotension which characterizes overmedication with barbiturate results in oliguria or anuria, and interrupts an important channel for excretion of these drugs.

Peripheral Autonomic Effects of Barbiturates. The barbiturates have a number of actions on organs innervated by the autonomic nervous system. These differ with the individual drug and with the species investigated. At present it cannot be stated with certainty what rôle, if any, the effect on autonomic structures plays in the clinical use of the barbiturates. Only a few of the accumulated experimental facts can be presented. A number of the barbiturates, given in anesthetic doses to animals, depress the electrical excitability of the vagus nerve to the heart, in some cases to the extent of complete block (Lieb and Mulinos, 1929; Garry, 1930; Koppanyi and coworkers, 1935). This parasympatholytic effect does not occur after the administration of thiobarbiturates, in which instance the cardiac responsiveness to vagal stimulation may even be enhanced (Linegar and associates, 1936; Gruber and coworkers, 1938). Although evidence suggests that the barbiturates have a curare-like action on vagal cardiac ganglia, they may also directly depress postganglionic fibers. Similarly, amytal has been reported to prevent the response of the submaxillary glands to stimulation of the chorda tympani (Stavraky, 1931), but here the action appears to be directly on the secretory cells whose response to acetylcholine as well as to nerve impulses is blocked by barbiturates.

Barbiturate anesthesia also interferes with the demonstration of the release of chemical mediators during nerve stimulation. For example, amytal and dial may interfere with the demonstration of the liberation of sympathin into the blood stream. Barbiturates have a markedly depressant or even paralyzing action on the proprioceptive mechanisms regulating vasomotor tone (Bouckaert and Heymans, 1937). Finally, the respiratory phenomena such as coughing, sneezing, hiccuping and obstructive spastic adduction of the vocal cords seen during clinical anesthesia with intravenously administered short-acting barbiturates may be due to hyperactive respiratory reflexes resulting from a central stimulatory effect on the vagus (Burstein and Rovenstine, 1938), and it has been suggested that atropine or scopolamine be administered prior to all such anesthesias.

Metabolic Rate and Body Temperature. The barbiturates tend to reduce somewhat the basal metabolic rate, although the effects of hypnotic doses in man have been insufficiently studied in this respect. Anderson, Chen and Leake (1930) reported that hypnotic doses of barbital, neonal, ipral and phanodorn, but not of amytal and phenobarbital, produced some decrease in oxygen consumption. Anesthetic doses of barbiturates, however, definitely lower oxygen consumption (Dameshek and coworkers, 1934; Shapiro, 1937). The usefulness of the barbiturates in patients with hyperthyroidism is based not on any specific effect on the elevated metabolic rate but rather on the sedative action.

Liver. Hepatic function is unimpaired by therapeutic doses of the barbiturates. Anesthetic doses of amytal, for example, cause no significant depression of hepatic function as measured in dogs and human beings by the bromsulfalein dye excretion test (Bourne and associates, 1930). In patients with liver damage, large doses of barbiturates may further injure the liver. The rôle of the liver in the detoxification of barbiturates is discussed under the fate of these drugs.

Miscellaneous Effects. The *uterus* is relatively resistant to the depressant effect of the barbiturates on smooth muscles, and hypnotic doses do not significantly impair uterine activity during labor. Full anesthetic doses, on the other hand, definitely decrease the force and frequency of uterine contractions (Gruber, 1937). More important in regard to the clinical use of barbiturates during labor is the depressant effect of the drug on the respiratory center of the infant, the placenta offering no barrier to the ready passasge of the chemical to the fetus.

The *cerebrospinal fluid pressure* is not influenced by hypnotic doses of barbiturates but may be decreased by larger amounts. Whereas Myerson and Loman (1932) found that amytal anesthesia in man caused no change in intracranial pressure, Horsley (1937) reports that of 100 patients anesthetized with the short-acting barbiturates, 99 manifested a fall of cerebrospinal fluid pressure to an average of about one-half of its previous value, this fall being succeeded by a slow rise.

The response of the *blood sugar* to medication with barbiturates varies considerably, dependent upon the particular drug selected, the dose and route of administration, the species being studied and the previous diet. In man, soporific doses do not significantly or consistently alter the level of blood sugar and these drugs are not contraindicated in patients with diabetes mellitus. The formed elements of the *blood* and the hematocrit are not significantly altered by hypnotic doses of barbiturates, but Searles (1939) has shown that amytal anesthesia in dogs causes a marked decrease in hemoglobin, erythrocyte count and cell volume, effects abolished completely by splenectomy and probably due to splenic dilatation.

Habituation and Tolerance. Addiction to the barbiturates, in the strict sense of the word, probably does not occur. Habituation, in contrast, is not infrequent and certain patients may experience craving and psychic disturbances after the barbiturate is withdrawn (*see* Lowy, 1934). This phenomenon, however, is rather characteristic of the hypnotic-sedative group of drugs. From an analysis of hospital data, Hambourger (1940) found that barbiturate "addiction" was fairly common, accounting for approximately one-tenth of all cases of drug addiction (excluding chronic alcoholism) received by hospitals in larger cities. However, only a third of the patients for whom information was recorded developed craving when the barbiturate was withheld, and none showed serious withdrawal symptoms. The control by state laws of the sale of barbiturates is an important factor in the prevention of their habitual use without medical supervision. At the present time, 27 states have laws regulating the sale of barbiturates (*see* the Bureau report, 1940).

Although a number of investigators have reported partial tolerance to occur in animals after the prolonged administration of barbiturates, a significant degree of tolerance to the barbiturates does not develop (*see* Stanton, 1936), and prolonged administration in human beings usually fails to diminish, or decreases only slightly, the hypnotic effects. Similarly, the toxic dose is not appreciably elevated after chronic medication. Clinical observations are borne out by some of the results of animal experimentation. For example, Swanson and coworkers (1937) noted no evidence of tolerance, withdrawal symptoms or decreased toxicity after a six-month period of administration of sodium amytal to dogs and monkeys.

Routes of Administration. *Oral.* The oral route of administration of barbiturates is the best from the standpoint of simplicity, safety and expense to the patient, and should be employed whenever possible. Other routes are resorted to only when special indications for their use exist. All the barbiturates (including thiobarbiturates) are satisfactorily absorbed from the intestinal tract, and only when the patient is moribund or uncooperative, or when the rapid onset of anesthetic effects of the drugs is desired, is parenteral administration used.

Rectal. The rectal administration of barbiturates is occasionally indicated, as in infants or in patients who are vomiting. The drug may be given in the form of a suppository or the soluble sodium salt may be incorporated in a retention enema. Thiobarbiturates are not given by the rectal route.

Subcutaneous and Intramuscular. When a rapid onset of action is required, as in patients with convulsions, the soluble sodium salts may be injected hypodermically. For this purpose, a 10 per cent sterile solution is employed. The solutions are not irritating when injected intramuscularly, provided the thiobarbiturates are not employed. The latter cannot be given subcutaneously or intramuscularly.

Intravenous. This route is by far the most dangerous and is reserved either for emergencies or for the production by competent anesthetists of surgical anesthesia of short duration. Once the drug has been injected, the degree of anesthesia can no longer be controlled by the physician, because elimination of the drug from the body is relatively slow. Therefore, the moment to moment control of anesthesia which characterizes the use of inhalation anesthetics and which accounts for their safety and preference, is lacking when the intravenous route is employed for barbiturates. When inhalation anesthesia is given, the amount of anesthetic to be used is readily ascertained from the response of the patient and the physical signs existing at any one moment. Withdrawal of the anesthetic results in a rapid lightening of the degree of depression. When barbiturates are injected intravenously, however, it is most difficult to judge in advance the amount to be given, and individuals vary considerably in their response. Reliance cannot be placed on fixed doses based on age and weight, and considerable experience is required to judge the amount to inject from the physical signs observed while the patient is entering surgical anesthesia. It must be remembered that in order to produce anesthesia, from 50 to 70 per cent of the fatal dose of barbiturate is administered.

The injudicious use of barbiturates by the intravenous route has resulted in a number of unnecessary accidents and deaths. An alarming fall in blood pressure to shock levels is sometimes observed, especially if the injection is performed too rapidly. Serious depression of the respiration is a constant danger of overdosage. The apparent ease of administration of an anesthetic by the intravenous route should not tempt one who is not thoroughly experienced in this field to employ barbiturates for intravenous anesthesia. The Council on Pharmacy and Chemistry in 1939 accepted for inclusion in N.N.R. barbiturates (pentothal) designed for use as intravenous anesthetics but properly warns that such use is potentially dangerous, should be undertaken only by experts for short operations and that facilities to combat respiratory and cardiovascular depression should be available. The value, dangers, contraindications, and technic of administration of pentothal sodium for intravenous anesthesia have been authoritatively reviewed by Ruth, Tovell, Milligan and Charleroy (1939).

As an example of the technic employed, that advised for pentothal sodium (N.N.R.) may be cited. Two to three cc of a five per cent solution (from 0.1 to 0.15 gram) are injected in approximately 10 to 15 seconds. The injection is then stopped in order to permit the complete effect to become apparent, which requires about 30 seconds. If relaxation has not occurred, an additional two or three cc may be injected at the same rate as before. If necessary, added increments of drug may be given at suitable intervals in order to maintain adequate anesthesia. The stages of anesthesia observed have been discussed.

Absorption, Fate and Excretion. *Absorption.* Absorption of the barbiturates occurs readily from the intestinal tract. The speed of absorption varies with the individual drugs; in general the rate is slower for the long-acting members and faster for the short-acting ones. Absorption also occurs readily from the rectum, subcutaneous tissues and muscles.

Fate. The distribution of the barbiturates in body tissues and fluids is poorly understood. After intravenous injection, the drug remains in the blood in detectable amounts for only a few minutes. Concentrations found in the brain are no higher than in other tissues nor does selective accumulation of barbiturate occur in subcortical loci. Barbiturates readily cross the placenta and are distributed throughout the tissues of the fetus. Although barbiturates appear in the cerebrospinal fluid, in concentrations as high as 0.250 mgm per cent in persons taking large amounts with suicidal intent, there is no correlation between the degree of depression and the barbiturate level (Kozelka and Tatum, 1937).

Full information concerning the fate of each individual barbiturate in man is not yet available. The body possesses two methods of eliminating the drugs, *i.e.* destruction in the liver and excretion through the kidneys. A few barbiturates are largely excreted; others are completely destroyed in the liver, and still others are partly excreted and partly destroyed. The fate of a particular barbiturate evidently depends on its chemical configuration but one cannot predict from chemical structure exactly how the drug will be handled by the body. In general, however, the thiobarbiturates and those with complex cyclic radicles such as evipal are less stable and almost completely destroyed in the liver. Barbiturates with short alkyl radicles are more apt to be stable and excreted in the urine.

Rôle of the Liver. Those barbiturates which are destroyed in the body undergo side-chain oxidation in the liver. The degradation products may appear in the urine, and as a rule have entirely lost their anesthetic potency, as shown for amytal, pentobarbital and ortal by Brundage and Gruber (1937). Destruction in the liver is the basis for the evanescent effects of the short-acting and ultra short-acting barbiturates. The importance of the liver in determining the duration of action and degree of depression resulting from a given dose of barbiturate has been demonstrated clinically and experimentally in a number of ways, all of which emphasize the necessity of knowing the fate of drugs in the body before one can give them with safety. For example, it has been reported that patients with impaired hepatic function have remained deeply anesthetized for many hours from a dose of evipal which in normal persons results in anesthesia for only fifteen minutes. Obviously, individuals with liver disease should not be anesthetized with barbiturates which depend for their intensity and duration of action on rapid destruction by the liver.

Similarly, Koppanyi and associates (1936) have shown that rabbits and cats, given pentobarbital and phenobarbital twenty-four hours after recovery from the effects of two hours of chloroform anesthesia, remain deeply depressed for long periods and may even die from doses which are only one-half the average fatal dose. Obviously, damage to the liver by chloroform prevents adequate detoxification of barbiturates. Furthermore, phenobarbital is a drug which also depends on the kidney for its excretion, but despite this alternative channel of elimination poisoning results when severe liver injury is present. Likewise, Pratt (1933) found that rabbits with livers injured by carbon tetrachloride or phosphorus, to the extent that bromsulfalein excretion was impaired, were very susceptible to the depressant action of pentobarbital, whereas the duration of action of barbital was not altered. Pentobarbital is almost completely destroyed by the liver in contrast to barbital which is largely excreted unchanged in the urine. Cameron and Saram (1938) verified this observation in rats with liver damage due to carbon tetrachloride by showing that the animals were more susceptible to the short-acting barbiturates—pentobarbital and evipal. When liver regeneration occurred, the susceptibility disappeared but if the pre-cirrhotic stage due to progressive liver damage was reached, the depressant action of the drugs was greatly enhanced.

Renal Excretion. Those barbiturates which escape destruction in the liver in smaller or greater degree are eliminated in the urine. Small amounts may appear in the milk after ingestion of large doses (Tyson and coworkers, 1938). Renal excretion occurs rather slowly, however, and this accounts for the longer duration of action of those members which are in good measure dependent on the kidneys for their elimination, such as barbital, phenobarbital, dial, ipral and alurate. After oral administration in man, from 65 to 80 per cent of barbital as such can be recovered in the urine, 30 per cent of dial, 25 per cent of phenobarbital and from three to eight per cent of amytal. Other barbiturates have not been adequately studied quantitatively in regard to their renal excretion.

The rather slow rate of excretion of barbiturates is the basis for the cumulative toxicity which occurs from their continued use. For example, in normal human beings, traces of barbital are still detectable in the urine nine days after ingestion of a hypnotic dose. Only eight per cent is eliminated in the urine in the first 12 hours, 20 per cent in 24 hours and 35 to 65 per cent in 48 hours.

When renal function is impaired, those barbiturates which depend upon the kidney for elimination may cause severe depression and poisoning. Thus it is important to know the status of renal function in order safely to prescribe a barbiturate. Argy, Linegar and Dille (1936), for example, have compared the excretion of barbital in normal and nephropathic subjects. Whereas nine normal individuals excreted an average of 14 per cent of 1.12 grams of barbital within 24 hours, eight nephropathic patients, given the same amount of drug, excreted an average of only six per cent. They noted in addition that barbital tended to cause oliguria in the latter group. The experiments of Hirschfelder and Haury (1933) on nephrectomized rabbits showed that barbital and phenobarbital, in particular, produce prolonged anesthesia and depression lasting until death whereas control rabbits recover in from 11 to 13 hours. Employing dogs, cats and rabbits with severe experimental nephrosis, Murphy and Koppanyi (1934) found that the animals did not recover from barbital and died in coma. Recovery did occur, however, from anesthesia produced by barbiturates less dependent than barbital upon the kidneys for elimination, such as pentobarbital, neonal, sandoptal and pernoston. Similarly, Gruber and Brundage (1937) found that nephrectomized dogs recovered as readily as did normal animals from anesthesia by ortal, a barbiturate which is destroyed by the liver. In a further study, Koppanyi, Murphy and Gray (1934) found that chickens eliminate barbital so slowly that they respond as do nephropathic mammals and die in coma from respiratory failure. They recover, however, from anesthesia produced by phenobarbital, pentobarbital, neonal and pernoston.

In *summary,* it may be stated that the ability of the liver to destroy barbiturates and of the kidney to excrete them determines both the duration of action and the toxicity of these compounds. Each member of the group is handled by the body in a distinctive manner, and the physician must know the fate and excretion of the drug he selects in order to employ it with safety. This is especially true when chronic medication is prescribed or when large doses are given parenterally.

Margin of Safety. For most groups of potent medicinals, the margin of safety is a major consideration in the selection of one drug in preference to another. However, it is highly problematical, whether significant differences in margins of safety exist between the various barbiturates. Some investigators, on the basis of experimental work on animals, are inclined to believe that there are detectable differences in therapeutic ratios among the barbituric acid derivatives. Others, however, do not agree with this opinion and believe that toxicity runs parallel to hypnotic potency. For example, it has been learned that, in order to produce a given degree of anesthesia in animals, the same percentage of the fatal dose had to be given regardless of the barbiturate selected. It must be granted that it is most difficult to measure small differences in grades of central depression in laboratory animals, and that the calculation of therapeutic ratio depends on the accuracy of such a measurement. It must also be conceded that the vast amount of clinical evidence available does not warrant the view that barbiturates differ from each other in margins of safety.

It would seem, therefore, that the doses of the various barbiturates required to produce sedative, hypnotic and anesthetic grades of depression bear a rather fixed relationship to the minimal fatal dose. Although the relation of chemical structure to pharmacological action is not always predictable, it would appear that attempts to obtain barbituric acid derivatives with appreciably higher margins of safety than those now available are not likely to meet with success, and that as more potent compounds are produced it will be found that their toxicities are also proportionately increased. The Council on Pharmacy and Chemistry has succinctly stated the prevailing opinion on this question as follows, ". . . there is no satisfactory evidence that the margin of safety between therapeutic and toxic doses of these (*barbituric acid*) derivatives is wider than in the case of barbital itself." In clinical practice, therefore, the physician need not at present be concerned about the therapeutic indices of the barbiturates but rather he should look to other factors for his selection, particularly the duration of action desired.

Choice and Classification of Preparations. A confusingly large number of barbiturates are available for clinical use. The safest guides to follow are the patient's requirements and the duration of action desired (Fitch and Tatum, 1932). Factors of idiosyncrasy and contraindication must be observed. It is urged that the physician become well acquainted with a few well-known and adequately studied barbiturates, particularly those included in the N.N.R., and use these as occasion demands rather than prescribe promiscuously each new compound that is placed on the market, often without sufficient experimental or clinical appraisal.

For clinical purposes, barbiturates may be classified into four main groups, depending upon their duration of action, as shown in Table 6. In general, speed of onset of hypnotic effects after oral administration and rapidity of recovery parallel the duration of somnifacient action.

TABLE 6

CLASSIFICATION OF BARBITURATES ON BASIS OF DURATION OF HYPNOTIC ACTION *

LONG-ACTING	MODERATE DURATION	SHORT-ACTING	ULTRASHORT-ACTING **
Alurate	Amytal	Evipal	Evipal
Barbital	Ortal	Seconal	Pentothal
Dial	Pentobarbital		Thio-ethamyl
Ipral	Pernoston		
Neonal	Phanodorn		
Nostal	Sandoptal		
Phenobarbital			

* Average soporific doses given orally.
** Anesthetic doses given intravenously.

Preparations and Doses. The barbiturates are odorless, white, crystalline powders which are slightly bitter to the taste, poorly soluble in cold water but soluble in alcohol and hot water. Saturated aqueous solutions are acid to litmus. The sodium salts are freely soluble in water and their solutions are alkaline to litmus. The barbiturates are marketed in tablet, capsule and suppository form, and can also be prescribed in solution. The N.F. contains an *Elixir of Barbital* (0.14 gram per four cc), and an *Elixir of Phenobarbital* (0.016 gram per four cc). These two elixirs are the only official solutions of barbiturates. Several of the sodium salts used for parenteral therapy are marketed as dry powders in sterile ampules, to which sterile water is added to effect solution before use, because of the instability of the sodium salts in aqueous solution.

The average adult *hypnotic* doses of the several barbiturates are given in Table 5. Many factors which determine the efficacy and safety of this average dose have already been discussed, and others will be described. The *sedative* dose is usually about one-third to one-fourth of the hypnotic dose, and may be repeated three or four times daily.

Barbiturate Poisoning. Poisoning by barbiturates may occur accidentally in the course of their therapeutic use or with suicidal intent. The wide and promiscuous sale of this class of sedatives provides ample opportunity for their employment in suicides. As Hambourger (1939) has pointed out, more than two million doses of barbiturates are sold daily in the United States. Suicide has its styles, and the use of hypnotic drugs, especially barbituric acid derivatives, is currently in vogue. The national incidence of suicide by means of barbiturates (1932–1936) is 4.2 per cent of that for all poisons (except gases), and the incidence in large cities ranges from two to 16 per cent. Accidental poisoning is especially likely to occur when the barbiturates are used for intravenous anesthesia by persons not sufficiently experienced in this highly specialized field. Occasionally, idiosyncrasy is the basis of the intoxication. Richards (1934) has reported three cases of acute barbiturate poisoning due to what he has called "automatism." Failure of the drug to produce sleep may cause a twilight zone during which the patient does not remember having already taken the medication and he may unwittingly ingest all the remaining tablets. An incorrect diagnosis of suicide may be given if death results from such accidental intoxication.

Death from ordinary therapeutic doses is practically unknown. In an examination of the pertinent literature by Gillespie (1934), no case was found on record in which either a single dose or repeated doses of average therapeutic size caused death in the absence of complicating factors. The rare cases of marked idiosyncrasy, such as fatal skin reactions, of course, are excluded. Severe poisoning usually occurs when an amount of barbiturate has been ingested which is five to 10 times the full oral hypnotic dose. The fatal dose varies with many factors and cannot be stated with certainty, but when over 15 times the ordinary hypnotic dose has been absorbed, it usually will prove extremely difficult to save the patient's life. The fatality rate in hospitalized cases of acute barbiturate poisoning is over seven per cent (Hambourger, 1940), and may rise to 15 per cent in severely poisoned cases.

Acute Poisoning. Symptoms and Signs. These are referable especially to the *nervous* and *cardiovascular* systems. When intoxication is fully developed, extreme lethargy, deep sleep or coma is characteristic. A period of excitement and delirium accompanied by hallucinations may occasionally precede the depression of the nervous system. Respiration is affected early, the respiratory rate is slow and the minute volume considerably decreased. Cheyne-Stokes rhythm may be present. Prolonged respiratory depression and the consequent anoxia adversely affect the cardiovascular system. The capillaries may dilate widely, become increasingly permeable and shock may result. Shallow respiration coupled with a low blood pressure favors the onset of hypostatic pneumonia. The activity of the reflexes conforms in a general way to the intensity of the central depression, but the deep reflexes are occasionally maintained for some time despite coexistent coma. The Babinski great toe reflex is often positive. The pupils react to light, as a rule, and are somewhat constricted, though at times they may be dilated. Occasionally, they are pin-point in size, as in morphine poisoning, and unresponsive to light.

The *blood pressure* does not fall until relatively late in the course of poisoning unless the drug has been injected intravenously in toxic amounts. Under this circumstance, the blood pressure falls rapidly to shock levels. After the oral ingestion of a barbiturate, however, the fall in blood pressure is due in large measure to the anoxia resulting from the decreased pulmonary ventilation. In severe grades of intoxication, direct depression of the vasomotor centers and a direct toxic inhibition of smooth muscle tone of smaller blood vessels also contribute to the hypotension. The pulse is rapid and weak.

As a result of the low blood pressure and possible central actions, *urine formation* is decreased or suppressed. This fact is of therapeutic importance because certain barbiturates cannot be detoxified and recovery from their effects is dependent upon adequate renal function. *Body temperature* falls and the *skin* is cold, moist and cyanotic.

The *diagnosis* of barbiturate poisoning is made from the history and physical examination, but differentiation from poisoning by other central nervous system depressants or from coma due to other causes may at times be difficult. Identification of the poison in the stomach contents or urine, or in the viscera after death may be required for medicolegal purposes, and fairly specific and quantitative methods for such identification are available (*see* Brundage and Gruber, 1937; Kozelka and Tatum, 1937; Kozelka, Nelson and Tatum, 1939; Delmonico and Adams, 1939).

The *prognosis* depends on the amount of and the particular barbiturate ingested, the general health of the patient, the type of therapy instituted and the interval elapsing between the ingestion of the poison and the beginning of treatment. The longer the patient survives, the better is his chance for ultimate recovery, and the prognosis is more favorable if the patient survives for 24 or 36 hours. Improvement may be noted within one hour after specific antidotal measures are employed, but the patient may not be out of danger for four days or longer if a long-acting barbiturate is the cause of poisoning (Figure 13).

Death, if it occurs early, is usually the result of paralysis of the respiratory center. The shorter-acting barbiturates are particularly prone to produce death from respiratory depression. If death is delayed, vasomotor collapse and hypostatic pneumonia frequently are the causes of the fatal issue. Bronchopneumonia may occur in a patient who has regained consciousness and apparently recovered, and therefore a guarded prognosis is advisable. The cerebral changes which occur in fatal cases of acute barbiturate poisoning consist of morphological alterations of ganglion cells in the brain, often associated with neuronophagia but without marked macroglial or microglial reactive phenomena. The changes are diffuse, but somewhat more marked in the medulla, especially the olivary bodies. The lesions are non-specific and resemble those produced experimentally by a variety of organic and inorganic poisons. More important and dangerous is the occurrence of cerebral edema with distention of the subarachnoid space and the cerebral tissue spaces (Hassin, 1939).

Therapy. If the barbiturate has been taken orally, which is usually the case, the stomach should be lavaged well with warm water by use of the gastric tube. Emetics are seldom efficacious and may further add to the depression. A solution of potassium permanganate (1:2000 to 1:5000) may be employed as a lavage medium if available, but is effective only for dial and alurate and not for the more commonly used barbiturates—barbital, phenobarbital and amytal (Hatcher, 1935). Magnesium sulfate, 20 to 40 grams, may be left in the stomach at the termination of the lavage in order to hasten the passage out of the bowel of the unabsorbed poison.

Attention should be focused without delay on the maintenance of adequate respiratory exchange and blood pressure, and lessening of the degree of central depression. If breathing is markedly depressed, *artificial respiration* may be needed, and a Drinker respirator may be life-saving. If breathing has ceased but the heart is still beating, *oxygen* is preferably delivered through a tracheal catheter, if this is possible. Drugs available for stimulation of the depressed respiratory center are *caffeine with sodium benzoate, ephedrine, coramine, metrazol, picrotoxin* and *strychnine.* Atropine is not very effective as a medullary stimulant. The caffeine salt may be given intramuscularly in the dose of 0.5 gram, every hour or two as needed. Enemas containing strong, warm black coffee are also helpful. Ephedrine may be injected intramuscularly in the dose of 10 to 30 mgm and repeated every hour or two if necessary. Both ephedrine and caffeine also lessen the degree of central depression by stimulation of higher cerebral centers, and ephedrine in addition has salutary effects on the cardiovascular system.

Strychnine and picrotoxin benefit the patient not only by stimulating respiration but also by lessening the degree of coma through their actions on higher centers and by stimulating the medullary vasomotor centers. Strychnine, in particular, also increases the reflex activity of the spinal cord and antagonizes barbiturates in this locus. Strychnine may be given intramuscularly in the dose of from two to 10 mgm and repeated approximately every two hours, depending upon the severity of the poisoning and the response of the patient. On occasion, it may be given intravenously when the patient is *in extremis.* Picrotoxin may be given as described elsewhere (page 264), but the status of this drug cannot be accurately stated. It is not fortified by the accumulated body of clinical and experimental evidence that exists for the use of other analeptics, and it is somewhat difficult to obtain. Dramatic results have nevertheless been reported from its use in barbiturate intoxication. Coramine and metrazol may be employed but the former, at least, is not as dependable as the agents hitherto mentioned. The inhalation of carbon dioxide and oxygen offers another measure for the stimulation of respiration.

In Figure 13 is illustrated the use of ephedrine and strychnine in the treatment of a patient who took 4.75 grams of phenobarbital in an attempt at suicide. It is evident from a study of the figure and its legend that the amount of ephedrine and strychnine given and the intervals and routes of administration employed were selected to meet the urgency of the case and were altered as the patient's condition improved. The use of large doses of ephedrine and strychnine in this case is again illustrative of the general principle that the level of functional activity of the nervous system determines the amount of central stimulant or depressant drug which may be given with safety.

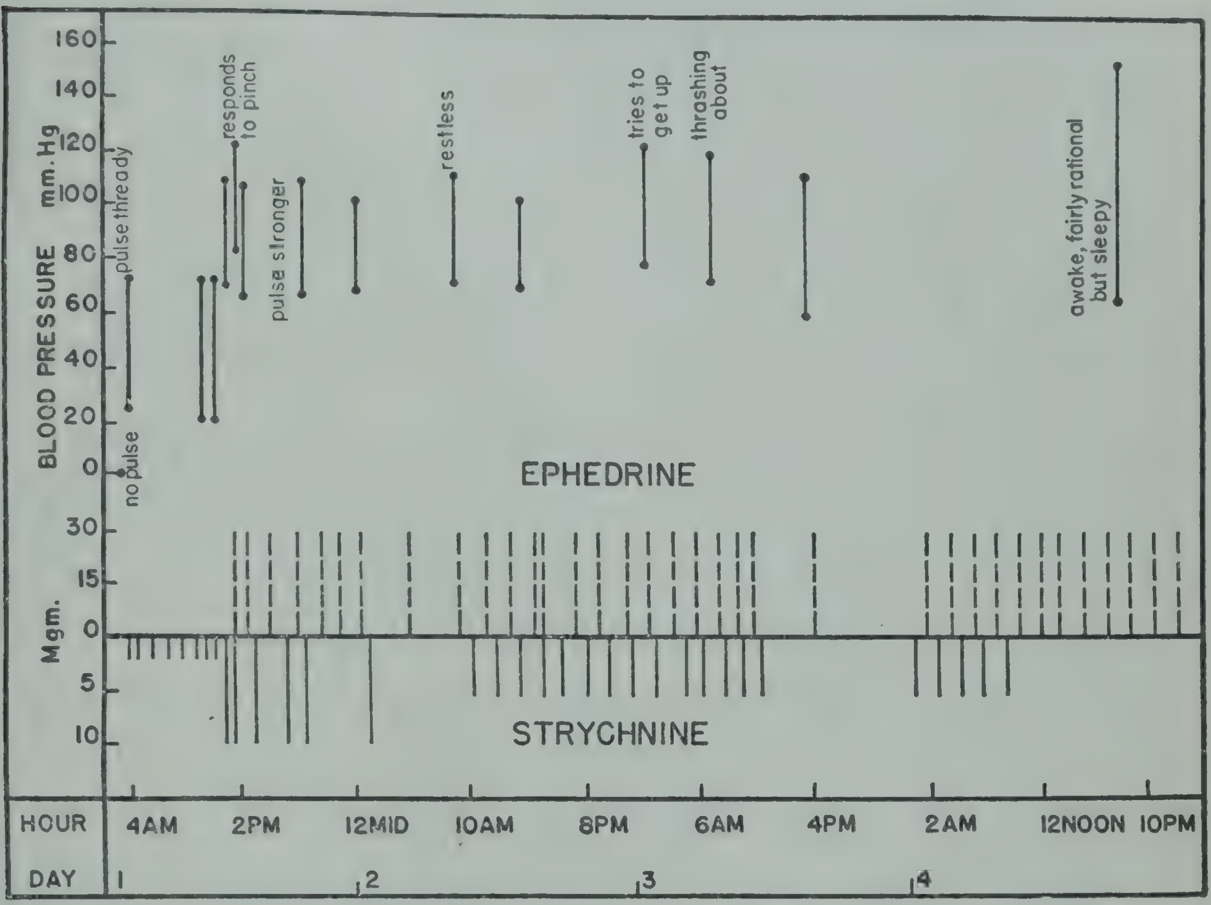

FIGURE 13. *Treatment of acute phenobarbital intoxication with strychnine and ephedrine.*

Female, aged 27. Six hours prior to hospital admission, the patient swallowed 4.75 grams of phenobarbital. Upon admission she was cyanotic and deeply comatose; respirations were shallow and slow; the pupils were "pin-point" and did not respond to light; there was no reaction to painful stimuli; the radial pulses were not palpable; the blood pressure was unobtainable and loud râles were heard over the lungs. Therapy with ephedrine sulfate intramuscularly and strychnine sulfate subcutaneously was instituted, intravenous injections being employed only for the first dose of ephedrine and for the first two 10.0 mgm doses of strychnine. Note that the doses and intervals employed were varied according to the patient's response, and that four days were required before antidotal medication could be terminated. The total amount of medication given over this period was 171 mgm of strychnine and 1200 mgm of ephedrine. Glucose and fluids were administered parenterally. (After Weiss, 1936. Courtesy of *International Clinics*.)

All the respiratory stimulants previously mentioned have a salutary effect on the cardiovascular system by improving pulmonary ventilation and relieving anoxia. In addition, most of them increase vasomotor tone by a central action. Ephedrine, in addition, has well-known peripheral effects on the heart and blood vessels which are of value in maintaining the blood pressure. If shock has intervened, however, reliance cannot be placed upon vasoconstrictor drugs and the measures outlined for the therapy of shock should be instituted. The intravenous use of a hypertonic solution of glucose, in particular, not only aids in maintenance of normal blood volume but promotes adequate urine formation and provides nourishment.

It is a matter of considerable importance whether diuresis hastens the excretion of a barbiturate and recovery from poisoning. The evidence available suggests that diuresis does neither. Nevertheless, adequate fluid intake should be maintained to insure optimal renal excretion, and if shock is present fluids of proper composition should be administered with the additional objective of restoring a normal blood volume. A five per cent solution of glucose in saline, saline hypodermoclysis and rectal drip may be employed for the administration of fluid and electrolyte to the comatose patient. Diuretic drugs are not indicated.

Additional measures in the treatment of acute barbiturate poisoning include keeping the patient warm, maintaining an adequate state of nutrition and preventing acidosis, careful nursing attention, and frequent changes in posture to prevent hypostatic pneumonia and decubitus ulcers.

Chronic Poisoning. Chronic poisoning may occur from the continued use of barbiturates in doses which allow for cumulative toxic effects. Thus, chronic poisoning is more apt to occur from the use of the longer-acting barbiturates. The syndrome is often bizarre and may offer a puzzling diagnostic problem unless the physician has a high level of suspicion for drug intoxication. If continued sedative effects are required, barbiturate medication should be alternated with hypnotics of a different chemical class.

Symptoms consist of drowsiness, a desire to sleep especially after meals, and slowness of thought, failing memory, incoherent speech, mental depression, confusion and disorientation. The more fully developed picture includes abnormal neurological findings as well as the mental phenomena mentioned. Vertigo, ataxia, nystagmus, diplopia, strabismus, difficulty of accommodation, dysarthria, paresis of the limbs, tremors, numbness and tingling, and increased, decreased or absent deep reflexes may occur. Many neurological syndromes may be closely simulated. In addition, gastro-intestinal disturbances occur and consist especially of anorexia, obstipation, foul breath and coated tongue. Skin rashes may develop. These may be erythematous, urticarial, purpuric or scarlatiniform in character. The rash caused by phenobarbital, in particular, may itch and it may resemble the exanthem of measles or of scarlet fever without the circumoral pallor. Pruritus is sometimes marked and the cutaneous lesions may be accompanied by fever. A rash may also appear on the tongue after prolonged use of phenobarbital. Rarely, exfoliative dermatitis may occur from phenobarbital and death may result (*see* Sweitzer and Laymon, 1937; Wile and Benson, 1940). The urine may contain albumin, casts, and occasionally hematoporphyrin; weight loss may be prominent, and anemia of the secondary type is not infrequent.

Treatment consists in stopping immediately all sources of ingestion of the offending agent and the institution of supportive and symptomatic therapy. Three weeks to a month may be required for the symptoms to clear, and recovery may be incomplete in elderly debilitated individuals. That a toxic effect on nerve cells may occur in chronic poisoning by barbiturates and account for the clinical picture is suggested by the delay in recovery and by the experimental work of Pickworth (1927), Seevers and Tatum (1931), and others. More definite evidence on this point is required, however, before the lesions which have been described can be accepted as specifically due to the chronic use of barbiturate, and some investigators have failed to find neurological lesions after prolonged administration of large doses of barbiturates in animals. The cause which prompted the patient to take the drug for a protracted period should be removed if possible.

Idiosyncrasy. Natural idiosyncrasy to the barbiturates usually manifests itself in the form of a *hangover,* excitement or pain. A hangover from relatively small hypnotic doses occurs especially in neurotic patients, particularly when the longer-acting barbiturates are employed. After the initial and characteristic period of depression has passed, lassitude, vertigo, nausea and vomiting, and diarrhea may be noted, and emotional disturbances and phobias may be accentuated. In some persons, barbiturates repeatedly produce excitement rather than depression, and the patient usually appears to be inebriated. Like other non-analgesic hypnotic drugs, the barbiturates when given in the presence of pain may cause restlessness, excitement and even delirium. Rarely the use of barbiturates results in localized or diffuse myalgic, neuralgic or arthritic pains especially in psychoneurotic patients with insomnia (Castin and Gardien, 1934; Weiss, 1936). Symptoms may be severe and last for days after the use of the drug is discontinued. The pains may appear in paroxysms, are most intense in the early morning hours, and are most frequently located in the region of the neck, shoulder girdle and upper limbs.

Acquired idiosyncrasy to the barbiturates consists chiefly of reactions which are allergic in nature, and occurs especially in persons who tend to have asthma, urticaria, angioneurotic edema, etc. Barbiturate-induced reactions in this category include localized swellings, particularly of the eyelids, cheeks or lips, erythematous dermatitis and bullous, cutaneous lesions. The reactions clear rapidly after cessation of the drug. There is abundant evidence that the barbiturates do not produce agranulocytosis, but they may be incorporated in patented nostrums which also contain aminopyrine, the agent most commonly causing agranulocytosis.

Contraindications. There are a number of contraindications to the use of barbiturates. They should not be prescribed for persons who manifest idiosyncrasy to them. For patients with impairment of renal function, those barbiturates which depend on renal excretion for their elimination should not be employed. The same holds true for individuals with impaired hepatic function with respect to barbiturates which depend on the liver for their destruction. It has been reported that phenobarbital aggravates the muscular rigidity accompanying Parkinson's disease to the extent that the patient may become bedridden (Ziskind and Ziskind, 1937). Confirmation of this observation, elucidation of the mechanism involved, and additional information concerning the other barbiturates are desirable.

Untoward responses attributable to the barbiturates are particularly likely to occur in patients with fever, hyperthyroidism, diabetes mellitus, severe anemia and congestive heart failure. However, none of these conditions represents an obligatory contraindication to the use of the barbiturates and excellent results are often obtained from their judicious administration.

Advantages of Barbiturates as Central Depressants. The barbiturates possess several advantages as depressants of the central nervous system, some of which are unique. Any degree of depression from the slightest sedation to deep surgical anesthesia can be obtained by a proper selection of drug, dose and route of administration, and the barbiturates lend themselves to a greater variety of uses than any other group of central depressants. The barbiturates can be administered by several routes, and their parenteral use provides definite advantages in emergencies. Given in large parenteral doses, these drugs have greater anticonvulsant properties than chloral hydrate or paraldehyde. Given intravenously, the ultra short-acting members are useful for producing surgical anesthesia of short duration. Phenobarbital has specific value in the symptomatic therapy of epilepsy. The barbiturates also are serviceable in protecting against the toxic effects of local anesthetics. Ordinary hypnotic doses have no untoward effects on vital functions of the body. Finally, the barbiturates are not disagreeable to the taste and can be dispensed in several forms for oral ingestion.

It should be noted, however, that the ease with which the barbiturates can be prescribed by the physician and taken by the patient is probably their greatest disadvantage in that they are often employed when other sedatives or other therapy might be preferable. Unfortunately such excellent hypnotics as chloral hydrate and paraldehyde have been considerably neglected since the barbiturates have become popular. Habituation probably is more readily developed to barbiturates than to chloral hydrate and paraldehyde due to the lack of any unpleasant taste or odor. It is highly to be desired that Federal or state laws be enacted to prevent the wide lay purchase and promiscuous use of barbiturates without physicians' authorization.

Therapeutic Uses

The barbiturates have numerous and important therapeutic uses. Most commonly, however, they are employed for their somnifacient and sedative actions.

Hypnosis. When administered for the purpose of inducing sleep, the barbiturates should be given at a time when their depressant effect will coincide with other factors promoting sleep. For example, from one-half to one hour is usually required for barbital and phenobarbital orally administered to be absorbed in sufficient amount to exert their initial action. From fifteen to thirty minutes are required for amytal and pentobarbital, and fifteen minutes or less for the short-acting drugs. It is important, therefore, that the patient be in bed and prepared for sleep in anticipation of this hypnotic effect. Natural dreamless sleep lasting from four to eight hours usually follows when the longer-acting drugs are used, and some lassitude may be noted upon awakening. The soporific effects of the short-acting members last only from two to four hours, and hangover is less frequent. If the patient experiences difficulty in falling asleep, the short-acting barbiturates may be selected. If, on the other hand, frequent awakening during the night is the chief complaint, the longer-acting drugs may be given. Some prefer to give the longer-acting barbiturates in two equal portions, the first dose two hours before bedtime and the second from one-half to one hour before retiring. This technic is calculated to prepare the patient for sleep by inducing drowsiness. The symptomatic relief obtained by the use of somnifacient drugs should not lessen the attempt to discover the causes of the insomnia or prevent the employment of the other reliable measures efficacious in this disorder. Repeated nightly use of barbiturates may result in habituation, and if hypnotic drugs are absolutely necessary over an extended period, medication with barbiturates should be alternated with the use of paraldehyde and chloral hydrate.

Sedation. For purposes of sedation, the barbiturates allow a wider range of therapeutic effects than is afforded by bromides. Sedation of any desired degree is obtainable within an hour or two, whereas bromide medication must be given approximately two days before its effects appear and the degree of sedation is difficult to regulate. Sedative doses of barbiturates are from one-third to one-fourth those used to induce sleep, and may be given three or four times daily, if necessary. Some of the more common conditions in which the sedative action of this class of drugs is desired include anxiety tension states, hyperthyroidism, essential hypertension, nausea or vomiting of functional origin, seasickness, acute labyrinthitis, pylorospasm in infants, chorea, cardiac failure, whooping cough, etc.

In hyperthyroid patients, the judicious use of barbiturates for sedation decreases muscular activity, lessens nervous excitability, and relieves worry. Care should be observed, however, because thyrotoxic individuals occasionally react poorly to barbiturates. The sedative action of these compounds is also of value in overcoming the central stimulating effects of ephedrine and benzedrine. The latter agents may thus be employed for their sympathomimetic effects or in myasthenia gravis without undue central excitation or insomnia resulting from con tinued medication.

In acute maniacal states and particularly in delirium tremens, the barbiturates are of value and it may be necessary to employ them in hypnotic or even anesthetic doses by the parenteral route. The sedative action of barbiturates is also helpful in the management of drug addicts undergoing withdrawal therapy. The prolonged use of barbiturates for sedation in patients with psychiatric disorders may result in confusion and accentuation of symptoms, and should be avoided. Although the barbiturates have been recommended to prevent nausea and vomiting in patients undergoing deep x-ray or radium therapy, their use may precipitate a toxicoderma due perhaps to cutaneous sensitization as a result of porphyrinemia. The lesion may be mistaken for roentgen erythema.

Potentiation of Analgesia. The potentiation by barbiturates of the analgesic action of the salicylate, pyrazolon and paraminophenol derivatives has been discussed. For combination with analgesics, the shorter-acting members are particularly suited. A large number of proprietary nostrums on the market for the relief of pain consist of just such a combination of drugs. The use of patented drug mixtures of secret composition or even of more legitimately marketed preparations containing fixed doses of ingredients can only be condemned. The physician can easily prescribe drugs of his own selection in such amounts as will best meet the changing needs of his patient. When the barbiturates are given in conjunction with analgesics, only about one-third of the hypnotic dose should be prescribed.

The barbiturates alone, in doses which do not cause unconsciousness, do not produce analgesia and they cannot be expected to induce sedation or sleep in the presence of pain. The barbiturates have been reported to give relief to a few patients suffering from syphilitic gastric crises or from migraine but such cases are exceptional.

Anticonvulsant Uses. The barbiturates are of great value in the symptomatic control of convulsions, such as occur in *tetanus, eclampsia, status epilepticus* and *cerebral hemorrhage.* They are also effective in combating convulsions caused by *cocaine, strychnine,* and *picrotoxin,* and those occurring during *general anesthesia.* The barbiturates with moderate or short duration of action are usually selected and are given intravenously if necessary. The amount injected is much more important than the particular barbiturate employed. Only enough should be administered to control the seizures, because when the convulsions cease the patient may sink into a deep coma if more barbiturate than absolutely necessary has been given. Usual doses for intravenous administration are sodium phenobarbital, 0.3 to 0.7 gram, sodium pentobarbital, 0.3 to 0.5 gram, and sodium amytal, 0.4 to 0.8 gram. The injection should be made slowly (30 to 60 mgm per minute), and the respirations and degree of muscular relaxation carefully noted. The drug may be repeated in amounts and at intervals determined by the patient's condition and response to therapy.

Prophylaxis Against Local Anesthetics. The specific value of the longer-acting barbiturates in the prevention of toxic reactions from cocaine and the synthetic local anesthetics is well established, and is fully discussed elsewhere (page 304). Should excitement or convulsive phenomena occur as a result of the local anesthetics, solutions of soluble barbiturates should be injected parenterally as described.

Control of Epilepsy. Phenobarbital was introduced for the symptomatic control of epilepsy by Hauptmann in 1912, and it is the only member of the barbiturate group effective for this purpose. Phenobarbital has advantages over bromides in that its action starts within an hour or two after ingestion, that it can be used for the control of acute or severe attacks, and that its use is not followed by the fetid breath, skin rash and sluggishness which frequently accompany bromide medication. Effective doses of phenobarbital, however, produce some measure of central depression and the drug is thus inferior in this respect to dilantin.

The adult dose of phenobarbital for the control of epilepsy varies considerably, but averages between 0.1 and 0.13 gram daily. This may be given in divided doses or the entire amount may be given before retiring, if nocturnal epilepsy exists, or in the morning for the diurnal form. Most failures are due to unsatisfactory regulation of the dose. The necessity for careful adjustment of dosage and the fact that very large amounts may be required by some individuals are emphasized by Lynch (1939) who reports a series of 116 epileptic patients in whom excellent results were obtained with phenobarbital. Doses of phenobarbital as large as 0.3 to 0.6 gram daily occasionally may be required to control seizures (Cohen and coworkers, 1940; Lennox, 1940). If these large doses cause drowsiness, dizziness and ataxia, such toxic effects may be dissipated by the concomitant administration of benzedrine (five to 25 mgm daily). This allows larger doses of phenobarbital to be employed than would otherwise be possible and the benzedrine apparently has no untoward effect on the incidence or character of the seizures (Ebaugh, 1940; Cohen and associates, 1940). Some patients may require medication for only five days of every week, thus decreasing the possibility of cumulative toxic effects. If for any reason the drug is discontinued, phenobarbital should never be stopped abruptly, because severe seizures or status epilepticus may result. The patient or his guardian should be warned concerning this point. If bromide or dilantin is being substituted, the dose of phenobarbital should be decreased gradually over a period of three or four days until the bromide or dilantin has had an opportunity to exert its effects. Medication should be continued until one or two years of freedom from seizures have elapsed, after which the dose may be decreased or even cautiously omitted.

The results obtained with phenobarbital are superior, in general, to those with bromide, although reports vary in this regard. Lennox (1940) states that of 766 noninstitutionalized epileptic patients receiving phenobarbital, 65 per cent were improved with respect to seizures and 30 per cent with respect to mentality; of 289 similar patients taking bromides, 53 per cent reported improvement regarding seizures, and 26 per cent regarding mentality. Grand mal responds better than does petit mal. Both the severity and frequency of seizures are decreased and the mental and physical well-being of the patient is correspondingly improved. Therapy, of course, is purely symptomatic. Careful psychological tests show that deterioration of the intellect does not occur as a result of medication with phenobarbital (Somerfeld-Ziskind and Ziskind, 1940).

Optimal doses of phenobarbital may be employed in conjunction with dilantin. The study of Cohen and collaborators (1940) appears to indicate that a striking synergism exists when phenobarbital and dilantin are used together, the combination being far more efficient in reducing the incidence of seizures than is either drug alone. Phenobarbital may also be administered together with a ketogenic diet, thus allowing the latter to be modified to a sufficient extent to make it more palatable.

Phenobarbital is less effective for petit mal and may, in large doses, make psychic seizures worse. Overdosage may cause symptoms resembling the mental or behavioral characteristics of psychic epilepsy. The investigations of Lennox and associates (1936, *et seq.*) have revealed that the abnormal electrical patterns, obtained with the electro-encephalograph, characteristic of petit mal are inhibited by phenobarbital or prevented from continuing sufficiently long to constitute a clinical seizure. According to these workers (*see* Lennox, 1940), epilepsy is a paroxysmal cerebral dysrhythmia. The rate of electrical waves recordable from the brain in grand mal is abnormally fast, in psychic seizures abnormally slow and in petit mal alternately fast and slow. Phenobarbital tends to slow the rate and hence is principally useful in grand mal and may aggravate psychic epilepsy. The actions of phenobarbital on the motor cortex, which may further explain the basis for the efficacy of the drug in epilepsy, have already been described (page 131).

A number of patients and even physicians have come to attach special virtue to the name "luminal" in the treatment of epilepsy. "Luminal" is merely a copyrighted trade name for a particular brand of U.S.P. phenobarbital. The drug possesses no special merit and its cost is much greater than that of the official preparation. The desirability of prescribing official drugs rather than expensive proprietary preparations cannot be too greatly stressed.

The use of drugs, including phenobarbital, in the therapy of epilepsy has been authoritatively reviewed by Lennox (1940).

Uses in Anesthesia. The barbiturates have a number of uses in anesthesia, including their employment for general anesthesia, basal anesthesia, preanesthetic medication and obstetrical amnesia.

(1) *General Anesthesia.* For selected surgical operations of brief duration, the ultra short-acting barbiturates may be employed for intravenous anesthesia provided the anesthetist or surgeon is adequately trained in this field. For example, intravenous anesthesia by barbiturates has been found of value for changing painful dressings and removal of sutures, encephalography, procedures of short duration in the oral cavity, brief manipulations of simple fractures, treatment of accidental wounds, etc. It is also of prognostic assistance in determining the result to be expected from neurosurgical intervention in patients with hypertension, Raynaud's disease, etc. The preparations employed are the thiobarbiturates and evipal (Table 5). The technic and dangers of intravenous anesthesia have been described. The procedure is especially contraindicated in patients with cirrhosis of the liver, jaundice, shock, hypotension, asthma, pulmonary disease and marked debilitation. Atropine or scopolamine should be administered before-

hand to diminish untoward respiratory reflexes and prevent spastic adduction of the vocal cords.

(2) *Basal Anesthesia.* The barbiturates may be employed prior to inhalation anesthesia in doses sufficient to cause basal anesthesia. The technic, advantages and uses of basal anesthesia have been described elsewhere. The oral or rectal route rather than the parenteral route is employed, and the amount administered is from two to four times the ordinary hypnotic dose. Larger doses should not be employed for the greater the part contributed by the barbiturate to the anesthesia, the more prominent are the many disadvantages manifested by nonvolatile anesthetics.

(3) *Preanesthetic Medication.* The barbiturates in combination with atropine or scopolamine are widely employed for preanesthetic medication, usually in place of morphine. The oral route is used and the dose is intermediate between the hypnotic dose and that for basal anesthesia. More frequently, one of the longer-acting members is administered the evening before operation in order to insure sleep. Some anesthetists combine morphine and barbiturates but this enhances the danger of respiratory depression. Others give a hypnotic dose of a barbiturate orally two hours before inhalation anesthesia and then inject the usual doses of morphine and atropine one hour later. When local anesthesia is used, preanesthetic medication with barbiturates not only allows tranquillity but also provides specific protection against toxic reactions from local anesthetics.

(4) *Obstetrical Amnesia.* The barbiturates are employed in obstetrics with the objective of rendering the patient tranquil and drowsy so that she will sleep between pains and not remember the ordeal, but nevertheless remain sufficiently conscious to assist in the delivery. Some obstetricians administer enough barbiturate to obtain partial anesthesia and analgesic effects, while others shun their use entirely, claiming that they are as prone to depress the fetal respiratory center as is morphine. For example, despite the favorable results reported for the use of pentobarbital in combination with various other agents in labor, approximately one-third of the babies in some series do not breathe immediately, whereas less than two per cent is the normal figure when no anesthesia is employed. Respiration in the newborn, however, is retarded by all central depressants given to the mother, and even when nitrous oxide is the only agent used, 20 per cent of the infants do not breathe immediately. Indeed, it is believed by some investigators that the main factor responsible for the large number of asphyxiated babies at birth is not the employment of analgesic-amnesic drug combinations (except for morphine) but rather the low concentration of oxygen used with nitrous oxide during the second stage of labor (*see* Clifford and Irving, 1937). The respiratory mechanism of the mother may also be affected adversely by the use of barbiturates, and from studies on the effects of these agents on normal parturient women, Sheldon (1939) has concluded that doses producing more than sedation during labor should not be employed. The barbiturates are frequently combined with morphine, scopolamine, paraldehyde, and volatile anesthetics. The details of this important and complex subject cannot be further discussed. The use of barbiturates in obstetrical analgesia should be entrusted to experts in this field.

CHAPTER 10

HYPNOTICS AND SEDATIVES

II. THE BROMIDES AND DILANTIN

THE BROMIDES

Historical. The element bromine was discovered in 1826 by Balard in the waters of the Mediterranean Sea at Montpellier, and nine years later the potassium salt of this element was introduced into the British Pharmacopeia for the treatment of splenomegaly. It was not recognized for some time that the bromide ion acted as a depressant of the central nervous system, and bromide salts were first used as a substitute for iodides in the therapy of scrofula, the close chemical relationship between the two elements having been recognized. Although no beneficial results were obtained, it was observed that administration of the bromide salts caused sedation. Inasmuch as potassium bromide was the preparation then employed, the depressant effect was attributed to the potassium ion, because intravenously administered potassium had been observed in the laboratory to cause depression and it was not realized that the oral ingestion of the cation could not possibly elevate the blood potassium sufficiently to duplicate experimental results obtained by its intravenous injection. If bromide had been employed in the form of its sodium salt, the pharmacological properties of the ion might have been recognized much earlier. By 1850, the actions of bromide on the nervous system were beginning to be recognized and in that year Huette published the first report of bromide intoxication. Bromide therapy of epilepsy apparently was recommended first by Sir Charles Locock in 1857. His reasoning was as follows: an unnamed person had tried potassium bromide on himself and found it to act as an anaphrodisiac, and since many cases of epilepsy were then thought to be caused by onanism, bromide should be used for epilepsy (quoted by Putnam, 1939). Locock employed the drug in fourteen cases with good results in all but one.

The typical central nervous system depression which results from the administration of the salts of bromine is now recognized as due to the bromide ion *per se*, and the particular cation to which it is linked does not influence this depressant action. It is likewise firmly established that only ionic bromide is active and bromine-containing compounds which do not release the element in ionic form (bromalhydrate, bromural, bromates, bromoform, etc.) do not share the action typical of the inorganic ionizable salts. Nevertheless, the basic mechanism of action of the bromide ion is obscure, some believing that the ion itself possesses central depressant properties and others contending that bromides act on the nervous system only by reducing the concentration of chloride ions, which are displaced by bromide.

Chemical Properties. All the inorganic salts of bromine which are employed clinically are very soluble in water, and moderately soluble in alcohol with the exception of the potassium salt. They are white crystalline powders which are saline to the taste. The chemical properties of bromides are well known and require no further discussion.

Laboratory Identification of Blood Bromides. The laboratory examination of body fluids, especially serum, for bromide is an extremely important procedure in the diagnosis of bromide intoxication, and the clinical recognition of this syndrome has been greatly facilitated by the advent of relatively simple chemical tests for bromide which can be conducted in the physician's office (Wuth, 1927; Diethelm, 1930; Hanes and Yates, 1938). The intensity of the reddish-brown color which develops when a solution of gold chloride is added to protein-free serum is an index of the amount of bromide present, and quantitative readings can be made against a standard in a colorimeter or by the use of a commercial comparometer. The significance of the height of the blood bromide level and the desirability under certain circumstances of routine examination of the serum for bromide will be discussed.

Pharmacological Actions. The only therapeutically useful property of the bromide ion is the depression of the central nervous system which it causes. Other effects of the ion in the body, such as those on the skin, mucosa and glandular secretions, are more correctly viewed as undesirable toxic side-effects.

Central Nervous System. The typical action of the bromide ion on the central nervous system is one of depression.Ordinarily, this action is controlled so as not to pass beyond a state of moderate sedation, but in large doses or with continued medication the bromides can cause marked depression of the cerebrospinal axis, even to the point of deep coma. In this respect the bromides share many of the actions of the depressant drugs of the hydrocarbon anesthetic series. Other tissues of the body react no differently to bromide than to chloride and are unaffected by concentrations of bromide which definitely alter functions of the nervous system.

In proper doses, the bromides cause mental calmness, sedation, drowsiness and sleep, if extraneous stimuli are minimal. Sleep induced by bromide medication is neither as deep nor as refreshing as that produced by the barbiturates, chloral hydrate or paraldehyde, and there may be a *hangover*. With larger amounts, lassitude becomes marked, intellectual processes are disturbed, thought and speech impaired, perception dulled and memory faulty. Still larger doses cause motor incoordination, lethargy, marked confusion and disorientation, delirium or stupor and then coma.

The early and empirical use of bromides for the control of the convulsive seizures of epilepsy focused attention on the action of bromides on the motor cortex. Albertoni, as long ago as 1882, demonstrated, by means of experiments on dogs, that adequate amounts of bromide could antagonize the effects on the motor cortex of direct electrical stimulation or convulsant agents. Neither bromide nor phenobarbital, however, is as selectively depressant to the motor cortex in epileptics as is dilantin. Merritt and Putnam (1938), for example, found that an amount of sodium bromide sufficient to prevent a cat from walking, elevated the convulsive threshold to electrical stimuli only about 50 per cent. An equivalent dose of phenobarbital trebled or quadrupled the threshold of excitation, but an amount of dilantin which increased the threshold to a similar extent caused no appreciable depression of other functions of the nervous system (Figure 15).

Mechanism of Action of Bromides. The mechanism of action of bromides on nerve cells is somewhat obscure. The tissue cells of the body, with the exception of the chloride-containing red blood corpuscles, are impermeable to both bromide and chloride. Therefore, the bromide ion must exert its pharmacological effects due to its presence in the extracellular fluids of the body, and nerve cells are apparently peculiarly sensitive to the substitution of bromide for chloride in their extracellular environment. Other tissues are relatively indifferent to the presence of bromide. For example, the chloride of the perfusion fluid of isolated hearts or other organs may be completely replaced by bromide without demonstrably harmful effects. The selective response of the cells of the brain to the bromide ion is unexplained.

The suggestion has been made that it is not the bromide ion in itself which depresses the functional activity of the cerebrospinal axis, but rather central depression results from the decrease in the concentration of the chloride ion which is displaced by bromide in the extracellular fluid. Unfortunately, it is almost impossible to obtain evidence on this point because as the bromide concentration rises, the chloride content of the extracellular fluids falls proportionately, the total electrolyte concentration remaining constant. A fall in the chloride content of the blood unassociated with bromide administration, however, does not produce typical central depression and for this reason it is believed that the bromide ion as such is the pharmacologically active agent in causing depression of the nervous system. Indeed, Hiatt (1939) has observed that the replacement of 50 per cent of the body chlorides by nitrate in dogs caused no observable changes in behavior.

Absorption, Distribution and Excretion. *Absorption.* The bromides are rapidly absorbed from the intestinal tract in a manner similar to chlorides. A high concentration of salts of bromine in the stomach may result in gastric distress and occasionally vomiting, due to local irritation caused by hypertonic solutions. For optimal absorption, therefore, bromides should be administered with sufficient water and preferably after meals.

Distribution. The bromides are distributed in the body in a manner almost exactly similar to chlorides. Thus the halogen can be found in all extracellular body fluids, secretions and transudates. Like chloride, bromide does not penetrate cell membranes. The exception is the red blood corpuscles, which are permeable to both chlorides and bromides. The concentration of bromide in erythrocytes is probably the same as in the serum (Palmer and Clarke, 1932; Van Dyke and Hastings, 1931). It is well known that the concentration of chlorides in body fluids remains quite constant under normal circumstances, and in man the average level of this anion in serum is approximately 355 mgm per cent (100 mEq). Inasmuch as the tissues of the body and the excretory organs do not distinguish between chloride and bromide, the administration of bromide results in the same adjustments as would occur if chloride had been given, that is, the total content of halogen in the extracellular fluid is kept at its normal value. When bromide and chloride constitute the halogen content of the body fluids, it is clear that their concentration ratio depends on the intake of each ion. Bromide displaces chloride during periods of bromide administration, and serious depletion of chloride may occur.

The bromide content of tissues and extracellular fluid has been studied especially by Mason (1936), Wallace and Brodie (1939), Smith and Walker (1938) and Weir and Hastings (1939). The ratio of bromide to chloride in the extracellular fluid of the tissues has been found to be the same as that existing in the serum. The ratio of bromide to chloride in the brain and cerebrospinal fluid, however, was found by Brodie and Wallace and by Weir and Hastings to be lower than that of the serum. It may be that equilibrium between the blood and the extracellular fluids of the nervous system occurs somewhat more slowly, thus giving a lower bromide content. It is possible that the cerebrospinal fluid is not in a simple physicochemical equilibrium with the blood and that this accounts for the lower bromide content of fluids of the nervous system.

Excretion. Bromides are excreted in the same manner as chlorides and thus almost exclusively in the urine. The kidney makes little distinction between the two halogens but rather functions to maintain the total halogen content of the extracellular fluids at a normal value. Bromides are therefore eliminated slowly. This can readily be appreciated from the consideration of what happens when one gram of sodium bromide is ingested. The kidneys will eliminate one gram of halogen-containing salt, the bromide to chloride ratio of the excreted salt being almost exactly that which exists in the serum. Inasmuch as the bromide content of the serum after a gram dose of sodium bromide is very low, much chloride and little bromide will be eliminated. If no more bromide is ingested, it will take many weeks before the ion is fully eliminated. If bromide medication is continued, the ion accumulates in the extracellular fluids until an equilibrium is reached, that is, until as much is excreted each day as is absorbed from the intestine. A patient receiving about six grams of bromide daily will reach equilibrium in approximately two weeks, depending on such factors as the chloride content of the diet, renal function, etc. Naturally, the lower the chloride intake the more rapid is the accumulation of bromide in the body for under such a circumstance the urinary excretion of halogen is minimal. Conversely, if the ingestion of chlorides is increased, the excretion of bromide is hastened, a fact which forms the basis for the therapy of bromide intoxication.

The ratio of bromide to chloride in the urine is not exactly the same as that in the serum, the kidney preferentially excreting chlorides (Hastings and coworkers, 1932; Mason, 1936). However, this preference is not marked and for practical purposes may be disregarded. Indeed, it has been denied that a preferential excretion of chloride occurs.

Small amounts of bromide appear in all secretions of the body. The tears, sweat, bile, milk, saliva and gastric juice thus contain the ion. The gastric juice of a patient receiving bromide medication contains hydrobromic acid, the acid-secreting cells of the mucosa of the stomach forming it from the bromide of extracellular fluid in a manner exactly similar to that for hydrochloric acid. The gastric mucosa secretes bromide somewhat preferentially over chloride, however, but this is not marked. In the alkaline juices of the duodenum, the hydrobromic acid is neutralized and the bromide is reabsorbed as the sodium salt. Bromides also cross the placental barrier with great ease, and the urine of infants born from mothers receiving bromide contains the ion.

Bromide Poisoning. *Acute.* Acute bromide intoxication is rare because amounts of the drug sufficiently large to elevate the serum bromide to a toxic level can hardly be ingested and retained without vomiting. Acute fatalities in man are thus unknown. However, in animal experiments the phenomenon is demonstrable and death occurs from respiratory failure and circulatory collapse.

Chronic Bromide Intoxication. Incidence. Poisoning from the continued use of bromides is known as *bromism.* The attention of physicians in the United States was first called to the high incidence of this condition by the publication of Wuth (1927). Despite the numerous papers subsequently appearing in the medical literature (Diethelm, 1930; Wainwright, 1933; Levin, 1933; Preu, Romano and Brown, 1936; Hanes and Yates, 1938; Curran, 1938; Gundry, 1939), chronic bromide intoxication occurs far too frequently. For example, from two to 10 per cent of the patients routinely admitted to psychopathic hospitals are found to be suffering from some degree of bromide intoxication. Of 238 routine admissions to the Phipps Psychiatric Institute at the Johns Hopkins Hospital, Wuth (1927) found 50 patients with bromide in their blood and 20 of these (nine per cent) showed signs of bromide intoxication. In 1000 consecutive cases admitted to the Colorado Psychopathic Hospital, Wagner and Bunbury (1930) recorded that 77 patients had blood bromide levels over 75 mgm per cent, and that in 44 of these the mental symptoms were due to or increased by bromide. Preu, Romano and Brown (1936) reported that 2.7 per cent of the patients admitted to the Psychiatric Clinic at the New Haven Hospital during 1935 showed signs of definite intoxication with bromide, and Preu (1939) later stated that 15 cases of *severe* bromide poisoning, including two deaths, were seen in 1800 consecutive admissions to the psychiatric service of the same hospital. Hanes and Yates (1938) state that approximately five per cent of admissions to psychiatric institutions are cases resulting from readily curable bromide intoxication. Most cases of chronic bromide poisoning admitted to psychiatric hospitals have been incorrectly diagnosed, and the reported incidence of bromide poisoning becomes higher as methods for testing the serum for bromides are adopted as a routine procedure. Neuropsychiatric patients should have routine blood bromide determinations.

There are several reasons why bromide intoxication occurs frequently. A physician's prescription is unnecessary in order to obtain the drug. A large number of nostrums which contain bromide do not reveal, by their trade names, the content of halogen. Many of these pass under the guise of "nerve tonics" and it is not unusual for patients to continue to take these patent medicines for the relief of the very symptoms of bromide intoxication which they produce. Finally, some physicians fail to appreciate that the continued use of bromides carries with it the definite possibility of cumulative poisoning, and that bromide is not always the benign, mild sedative which tradition would lead one to believe.

Symptoms. Symptoms of bromism may appear slowly or rather suddenly in the course of chronic bromide medication. Signs and symptoms are referable to the skin, glandular secretions, gastro-intestinal tract and nervous system. *Dermatitis* is common and is known as *bromide rash.* It starts most often as an acneform eruption on the face and at the hair roots, and may spread over the neck, chest and arms to involve the entire body. The dermatitis is occasionally indistinguishable from acne vulgaris. Severe skin lesions may appear in the absence of mental or neurological evidence of bromism, and the converse is also true. Indeed, only 25 per cent of the patients with bromism have cutaneous eruptions. Therefore, it is not necessary to have a bromide rash in order to have bromide poisoning, and a frank symptomatic psychosis due to bromide may remain undiagnosed unless this point is appreciated. The lesions of the skin may take unusual forms. A nodular type of lesion on the legs, known as nodose bromoderma, may be mistaken for tertiary syphilis and may develop into a sarcoma-like lesion. Pemphigus-like vesicles may appear and contain bromide in their exudate. Pustular lesions and ulcerations sometimes develop. Rarely, a bromide rash may appear on the tongue and hard palate.

The cause of the cutaneous eruptions is unknown. It has been claimed that the secretion of bromide in the sweat is the etiological factor and the unlikely suggestion has even been made that free bromine is perhaps split off in minute amounts in the acid sweat. However, it has been contended that the bromide rash begins in the papillary layer of the skin and not in the sweat glands which are involved only secondarily. The dermatitis may develop when the blood bromide level is still relatively low and, conversely, the skin may be clear despite the existence of high blood levels of bromide. It is said that persons with a seborrheic tendency have a predisposition to bromide acne.

Glandular secretions of the body are also affected in bromide intoxication. Excessive lacrimation and a mild conjunctivitis, resembling an acute coryza, may occur, as well as increased mucus secretion of the respiratory passages. These features are suggestive of the picture seen in iodism, but are not as marked as after iodide medication. The stimulation of the glands of the orbit, nose and broncho-respiratory tree may be due to the presence of bromide in their secretions.

Gastro-intestinal disturbances are sometimes prominent and are manifested by anorexia, foul breath, heavily furred tongue, sordes, constipation and gastric distress. The presence of hydrobromic acid in the gastric juice has already been mentioned, and may contribute to the gastro-intestinal symptoms. The lack of adequate intake of food and water results in rapid emaciation and dehydration. Low grade fever may also occur.

Mental and neurological disturbances are the most prominent features in bromide intoxication, and represent the most serious aspect of the syndrome. The signs and symptoms vary greatly from patient to patient, dependent upon constitutional and personality factors, and may take many bizarre forms, simulating closely almost every type of organic or functional mental or neurological disease. The earliest *mental symptoms* represent an extension of the therapeutic sedative action of the bromides, and consist of impaired thought and memory, drowsiness, disturbed consciousness with disorientation and emotional disturbances. In more severe cases. delirium, delusions, vivid auditory or visual hallucinations, violent mania, lethargy and coma may occur. The term "bromide psychosis" has arisen due to the frequency with which a symptomatic psychosis occurs in patients with bromide poisoning.

Neurological disturbances are also common, and are manifested in tremors of the hands, lips and tongue, speech defects, weakness, sluggishness of movement, motor incoordination, faulty gait, ataxia, increased, decreased or absent deep reflexes, positive Babinski great toe sign, decreased or absent superficial reflexes, especially of the mucous membranes, etc. The cerebrospinal fluid pressure may be elevated and in cases of severe intoxication papilledema may be present. The syndrome may simulate and has been mistaken for acute alcoholic intoxication, general paresis, tabes dorsalis, encephalitis, cerebral tumor, multiple sclerosis, uremia, and other entities. In the diagnosis of any bizarre nervous or mental disease, the physician should be suspicious that drug intoxication may exist, and bromides should be placed high in the list of possibilities. Patients suffering from depression, arteriosclerosis and fever are particularly likely to develop bromide psychosis from doses of the drug which do not appear excessive. Only by examination of the serum for its bromide content can the possibility of bromide poisoning be ruled out.

Correlation of Blood Bromide Levels and Symptoms of Bromide Intoxication. Bromide displaces chloride in the extracellular fluids ion for ion. The atomic weight of bromine (approximately 80) is about 2.3 times that of chlorine (approximately 35.5). The chloride content of the extracellular fluids of man is quite constant at 355 mgm per cent (100 mEq). If this value is reduced by replacement with bromides to the extent of 40 per cent, that is, from 355 mgm per cent to 213 mgm per cent (100 mEq to 60 mEq), extremely severe bromide intoxication is present and life may be seriously endangered. At this point, the blood bromide level would be 326 mgm per cent (40 mEq) $(142 \times {}^{80}/_{35.5})$.

There is no absolute correlation between the severity of bromide poisoning and the level of bromide in the blood. Many factors are concerned in determining whether a patient with a given level of blood bromide will show evidence of intoxication, among these being the general physical condition of the patient, the food and salt intake, the presence or absence of dehydration, vomiting, diarrhea and impaired renal function, the mental state, etc. For example, a patient who is cachectic, dehydrated and on a poor chloride intake may show severe symptoms of bromide intoxication when the blood bromides are only 100 mgm per cent (12.5 mEq), that is, when only 12.5 per cent of the blood chlorides have been replaced by bromide. Again, epileptic patients, who are properly managed, may continuously have blood bromide levels of from 100 to 125 mgm per cent (12.5 to 16 mEq) and note only mild sedation. However, the definitely "toxic zone" must be placed at blood bromide levels of 150 to 200 mgm per cent (19 to 25 mEq), and most patients with the latter concentration will show unmistakable evidence of poisoning. Indeed, extremely severe bromide psychosis has repeatedly been reported at this level. Bromide concentrations in the serum as high as 400 mgm per cent (50 mEq) have occurred, but these unusually high levels are not long compatible with life.

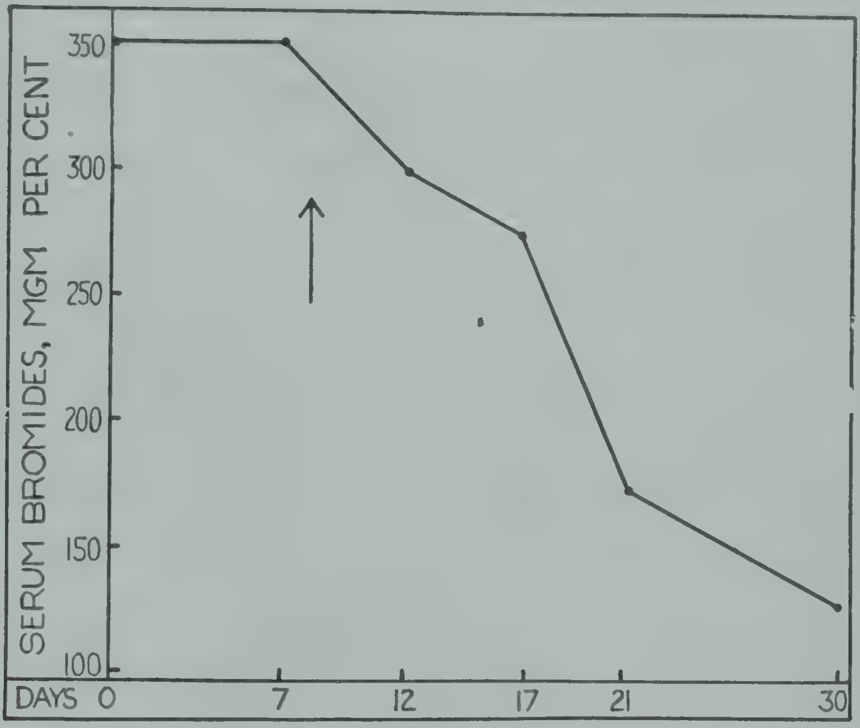

Figure 14. *The effect of the administration of sodium chloride on the rate of elimination of bromide.*

Arteriosclerotic patient, aged 47, with typical symptoms of bromide poisoning. The oral administration of sodium chloride (started at the arrow) hastens the renal excretion of bromides. (After Wagner and Bunbury, 1930. Courtesy of *The Journal of the American Medical Association.*)

In any patient in whom unexplained mental or neurological symptoms exist coincident with a blood bromide value of approximately 75 to 100 mgm per cent (nine to 12.5 mEq), the bromides must be held in high suspicion as the main or contributory cause of the syndrome until they are proved blameless. Withdrawal of bromide and administration of chloride are urgently called for, and the character of the response to treatment will often determine whether bromide was at fault. The urinary content of bromide does not offer a suitable guide in the detection of bromide intoxication.

Treatment of Bromide Intoxication. When the diagnosis of bromide poisoning is made or suspected, all possible sources of bromide ingestion should be investigated and removed. Specific therapy consists in the administration of sodium chloride in order to hasten the elimination of bromide (Figure 14). Sodium chloride is given by mouth, as a rule, but if this is impossible it may be given by hypodermoclysis or intravenous infusion of a sterile 0.9 per cent solution. The dose varies with the severity of the poisoning and the response of the patient, but from six to 12 grams should be given daily in divided amounts in addition to the sodium chloride ordinarily contained in the diet. Some workers experienced in the field believe that if the blood bromide concentration is very high (300 mgm per cent), the administration of extradietary sodium chloride to hasten the excretion of bromide should be delayed until the bromide level has started to fall spontaneously. The reason given is that an exacerbation of bromide intoxication may occur if large amounts of chloride are given. This point is in need of confirmation and adequate explanation.

The fluid intake should be kept at a minimum of 4000 cc per day, in order to correct dehydration if present, to insure diuresis and to prevent loss of body water as a result of the large doses of salt. Adequate intake of food should be assured, by gavage if necessary, in order to combat malnutrition so often associated with chronic bromide intoxication. Enemas and liquid petrolatum may be used to correct constipation. The skin lesions usually clear spontaneously and only the mildest of local measures are indicated. The use of sedatives is usually contraindicated although measures must be taken to combat extreme excitement and delirium. Cold wet sheet packs and continuous tub baths often will allay insomnia and excitement. Recovery requires from one to three or more weeks, when adequate chlorides are administered. When the blood bromide concentration is falling, symptoms of poisoning disappear at a level which is usually higher than that at which they appeared. After recovery, the patient should receive therapy for the underlying condition for which the bromides were originally taken.

Preparations, Doses and Administration. Many different *preparations* of bromide salts are available. These include the bromide salts of sodium, potassium, calcium, strontium, lithium, ammonium, etc. The chief differences in these compounds are their expense and bromide content, but the variation in content of bromide is not sufficiently great to be of practical importance. The official U.S.P. preparations are *Sodium Bromide, Potassium Bromide, Calcium Bromide* and *Ammonium Bromide.* The first two salts are also official in the B.P. Sodium bromide is perhaps preferable, being the least expensive and also the least irritating to the stomach. Ammonium bromide is likely to cause gastro-intestinal distress and is unstable, turning yellow on exposure to air and giving off free bromine. Furthermore, ammonium bromide is an acid-forming salt and may tend to cause acidosis.

A combination of bromides which is rather entrenched in medical tradition is *triple bromides* (*Tablets of Three Bromides,* N.F.; Erlenmeyer mixture), consisting of equal parts of the sodium, potassium and ammonium salts of bromide. It has absolutely no advantages except that it is usually elegantly prepared in effervescent tablets containing citric acid and sodium bicarbonate, which are not unpleasant to take. The N.F. also contains several syrups and elixirs of bromide salts. *Organic bromides* have been exploited for many years by certain drug firms as being less toxic than the inorganic salts. They are expensive and often contain little ionizable bromide. If a bromide preparation is non-toxic, it is also inert therapeutically, because the toxic effects are extensions of the therapeutic effects.

Bromides are always given by mouth, in the form of tablets, capsules, or in solution in syrupy vehicles. The vehicles which especially blind the unpleasant taste are the syrups of citric acid, orange, licorice, cocoa and raspberry, and aromatic syrup of eriodictyon. Medication should be given after meals, and ample water taken with each dose for the dual purpose of lessening gastric irritation and preventing dehydration due to the diuretic "salt action" of bromides.

The *dose of bromides* cannot be stated categorically. It depends chiefly on the end sought and the intake of chloride. Moderate sedation is usually obtained in adults who are in good physical condition from the administration of from three to five grams of sodium bromide daily, provided the patient is eating well. This same amount may prove toxic within a few days to a patient who is dehydrated, eating poorly or not at all, and who has poor renal function. The physician should be alert to the symptoms of bromide intoxication, and medication should not be given, as a rule, for a period of over two to three weeks when patients cannot be kept under surveillance. An exception must be made in the treatment of the epileptic patient whose regimen is well established, whose optimal dose of bromide has been determined, and whose response to therapy over extended periods of time is known. One should prevent the indiscriminate refilling of physicians' orders for bromide by placing the letters (N.R.) on the prescription (page 1310).

Therapeutic Uses. The bromides are valuable as sedatives and for the treatment of epilepsy.

Sedative Uses. Bromides were first introduced for *insomnia* by Behrend in 1864. The somnifacient effects of bromides, however, cannot be expected to ensue from a dose of two or three grams of a bromide salt administered before retiring. Depression of the central nervous system by bromides requires that a sufficiently high concentration of the ion be present in the extracellular fluid, and this is not obtainable from a single therapeutic dose of bromides. The continuous administration of the drug eventually results in sufficient sedative action to overcome sleeplessness, but this action is persistent and disappears only when the bromide level of the blood has fallen sufficiently low. For this reason, when rapid results are necessary, bromides are not the soporifics of choice and one relies on a barbiturate, chloral hydrate or paraldehyde.

For *chronic sedation* of a mild degree, the bromides are probably employed more frequently than any other therapeutic agent. They are serviceable to lessen anxiety and worry, to quiet patients with cardiac disorders or hypertensive vascular disease, to lessen reflex irritability in hyperthyroid states, to control seasickness and the vomiting of pregnancy, to lessen sexual hyperesthesia in nymphomania, satyrism and chordee and after circumcision in adults, etc.

Epilepsy. A special use of bromide is for the control of convulsive seizures in epileptic patients. Bromide salts were the first of the depressant drugs to be employed in epilepsy, and despite the large inroads made by the use of phenobarbital after its introduction in 1912 and more recently by the ketogenic diet and dilantin, bromides continue to be widely used. The anticonvulsant action of bromide depends upon depression of the motor cortex; but the absence of a high selectivity of action as compared to dilantin is apparent in the fact that a certain degree of sedation must be tolerated in order to obtain beneficial effects. Bromides cannot be employed in acute convulsive syndromes, such as strychnine poisoning and tetanus, because of the slow onset of action. The effects of bromide on the cerebral dysrhythmia of epilepsy recordable electro-encephalographically are similar to those of phenobarbital (page 149).

Bromides give only symptomatic relief in epilepsy by reducing both the number and intensity of convulsive attacks. Complete remissions lasting for one or more years occur in approximately 50 per cent or more of all persons with grand mal who are properly treated, but the exact percentage varies from series to series (*see* Pollock, 1938; Stone and Arieff, 1940; Lennox, 1940). Nearly all the remaining patients are benefited in some degree. The data of Lennox on the comparative value of bromide and phenobarbital in relieving seizures and improving the mental status of a large group of noninstitutionalized epileptic patients are given on page 148. Results are most striking when a patient who has had only a few seizures is treated by the use of bromides. The response to treatment is less satisfactory in petit mal; occasionally petit mal may appear after grand mal has been controlled with bromide, and then prove refractory to therapy. Large doses of bromides may make psychic seizures worse or may produce symptoms which resemble the mental or behavioral characteristics of psychic epilepsy. Treatment is less effective in those patients with focal attacks, or if injury or disease of the brain is the cause of the syndrome. In order to maintain an uninterrupted remission, therapy must be continued for years or even throughout life. The opinion held by some authorities that, after several years of freedom from convulsions, a patient may gradually diminish his medication is thought by others to be erroneous.

The dose of bromides for the epileptic patient is that which will keep him free of attacks and yet not cause undue discomfort from the prolonged use of the drug. Adults usually require from 1.0 to 1.3 grams three times daily, this dosage being increased or decreased according to necessity. A diet poor in chloride allows a given dose of bromide to reach more effective concentrations in the blood. The skin should be kept clean to lessen the incidence of bromide rash. Bromide therapy may be combined with phenobarbital medication or used as an adjunct to the ketogenic diet. If one returns to bromide therapy after a period of phenobarbital medication, the latter drug should not be stopped suddenly before the bromide concentration in the blood has been built up to an effective level, or severe seizures and even status epilepticus may result. Epileptic patients on bromide therapy usually carry blood bromide levels of from 75 to 100 mgm per cent, and concentrations of 125 mgm per cent should probably not be exceeded. Obviously, bromide medication is unsatisfactory in patients with status epilepticus or for the acute control of severe and rapidly recurring seizures. The effect of continued administration of bromide on the mentality of epileptic patients is much disputed. Lennox (1940) is of the opinion that persons who are mentally stable (whether epileptic or normal) can take moderate amounts of bromide with impunity, whereas those epileptic persons who are mentally unstable or have psychic variant seizures should better be given other medication. The use of drugs including bromides in the treatment of epilepsy has been reviewed authoritatively by Lennox (1940).

Contraindications. Bromides should not be used for patients with tuberculosis for the same reason that the employment of iodides is usually avoided (page 617). Bromides should also be used with great care, if at all, in patients with advanced arteriosclerosis, debilitation or cachexia, and dehydration. Delirium is readily produced by drugs in individuals with cerebral arteriosclerosis. When diarrhea, vomiting, poor chloride intake, anorexia, etc., are present, the administration of bromides in seemingly safe amounts may rapidly lead to bromide intoxication. In numerous clinical case reports, chronic alcoholism, dehydration and deficient diet played a definite rôle in the development of bromide intoxication. Poor renal function, as in patients with nephritis, also enhances the possibility of poisoning by bromide. Bromide may aggravate the cutaneous lesions of patients with dermatitis, especially acne and dermatitis herpetiformis, or cause an exacerbation of the symptoms of coryza or hay fever.

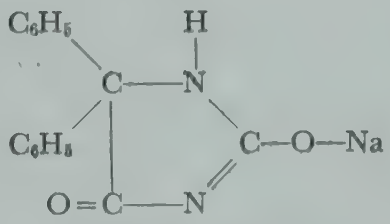
Obviously, no patient with an undiagnosed nervous or mental disturbance should receive the halogen until it is established beyond doubt (*i.e.*, by a blood bromide determination) that his illness is not due to previous bromide ingestion. Bromides should not be prescribed for unlimited periods unless the patient can be kept under close medical observation and an adequate intake of dietary chloride and fluid assured. Proper food and water intake is as important a factor as the exact dose of bromide ingested. Even then, the physician must constantly be on the alert for evidences of beginning intoxication. Bromides should not be prescribed for patients with severe excitement or agitation because the drug is not effective unless dangerously large amounts are given. Delirium due to infectious and toxic syndromes presents an added risk to the safe employment of bromides. Paraldehyde is to be preferred. Bromide has no rational place in the management of patients with depression. Bromides are not analgesic, and their use to allay pain may cause delirium. Inasmuch as bromide medication depresses both libido and potentia, the drug should not be employed when patients with tensional states complain of loss of libido.

The clinical status of bromide therapy has been well summarized by Wagner and Bunbury (1930), as follows: "We do not wish to leave the impression that we consider bromide harmful or even useless as a therapeutic agent. Any one who has had occasion to use bromide realizes that it can be an effective and valuable sedative. We do believe, however, that bromides are used much too indiscriminately and frequently produce harmful rather than beneficial effects. These harmful effects of bromide could be reduced to a minimum if physicians recognized the undesirable mental symptoms of bromide intoxication and were willing to use the simple method described by Wuth for determining the bromide concentration in the blood."

DILANTIN

Historical. Dilantin sodium is sodium diphenyl hydantoinate, a drug closely related to nirvanol. In an extensive experimental study of anticonvulsants by Merritt and Putnam (1938), dilantin sodium was found to possess the greatest anticonvulsant activity combined with the least hypnotic effect of the many drugs investigated. The experiments were conducted on cats and convulsions were produced by controlled and quantitated electrical stimuli (Putnam and Merritt, 1937). Dilantin sodium was found to be as anticonvulsant as phenobarbital but to lack the depressant effects of the latter drug. After preliminary toxicity studies on animals had been performed, Merritt and Putnam (1938) introduced dilantin sodium as an agent to control convulsive seizures in epileptic patients. The Council accepted dilantin sodium for inclusion in N.N.R. (*see* the Report of the Council, 1939).

Chemistry and Preparations. *Dilantin Sodium,* N.N.R., is the proprietary name for *sodium diphenyl hydantoinate,* the structural formula for which is as follows:



Dilantin Sodium

The close chemical relationship of dilantin to nirvanol is at once apparent, an ethyl group in the latter being replaced by a phenyl radical. This relationship accounts for the toxic side-actions noted with dilantin, many of which resemble those occurring with the use of nirvanol. Dilantin is also closely allied to the barbiturates, being a derivative of glycolyl urea instead of malonyl urea.

Dilantin sodium is a white, odorless, microcrystalline powder with a slightly bitter taste. It is marketed for oral administration in sealed capsules, each containing 0.1 or 0.3 gram of drug. Aqueous solutions are alkaline, and the drug is completely soluble in water only when the solution is adjusted to pH 11.7, thus making parenteral adminstration impracticable. The chemical is soluble in alcohol.

Pharmacological Actions. The pharmacological and toxicological effects of dilantin in animals have been reported by several investigators (*see* Gruber and coworkers, 1940; Haury and Drake, 1940). Toxic doses produce death by respiratory failure or asphyxia from convulsions, and elicit nystagmus, mydriasis, panting, hyperpyrexia, spastic gait, tremors of the neck muscles, salivation and vomiting, peripheral vasodilatation and fall in blood pressure, defecation with liquid stools, urination, and opisthotonic convulsions.

Doses in the therapeutic range have been shown to be innocuous for a large variety of laboratory animals and long-continued medication with such amounts are without apparent ill effect. Cats, dogs, rabbits and rats withstand massive single doses of dilantin administered orally. For example, the minimal lethal dose of dilantin by mouth for the rat is 1.6 grams per kg; for the rabbit, 3.4 grams per kg. Dilantin is considerably more toxic when administered intravenously or intraperitoneally.

The mechanism by which dilantin prevents electrically induced convulsions in animals and epileptic seizures in man is unknown. That the action is highly selective for the motor cortex is indicated by the fact that the drug apparently does not depress other functions of the brain. The threshold of corticomotor excitability in animals is raised two- to four-fold, whereas a dose of sodium bromide sufficient to prevent a cat from walking causes only a 50 per cent increase in the threshold. Similarly, an amount of phenobarbital causing an equivalent increase in the threshold to that of dilantin produces marked hypnotic effects (Merritt and Putnam, 1938) (Figure 15).

The data concerning the action of dilantin on convulsions experimentally induced in human beings is as yet meager. Frost (1939) found that the drug did not lower the convulsive threshold dose of metrazol administered intravenously in three insane patients. However, Goldstein and Weinberg (1940), employing a larger series of patients, concluded that dilantin diminished the frequency of convulsive phenomena induced in epileptic subjects by the subcutaneous injection of metrazol, particularly in those individuals with grand mal.

That dilantin may exert other effects than that on cortical excitability, however, is suggested by the facts that psychomotor equivalent attacks are relieved and that many epileptic patients become better behaved and more amenable to discipline after administration of the drug (Merritt and Putnam, 1938, 1940). The action of dilantin on the characteristic cerebral dysrhythmia underlying epilepsy is not fully known at present. Whereas phenobarbital and bromides prevent or abort the electrically recordable dysrhythmia of petit mal (page 149), dilantin may not necessarily improve the electroencephalogram of epileptic individuals who are, nevertheless, rendered free of seizures. On the other hand, the electrical record of patients who are abruptly and completely relieved of attacks, especially of the psychomotor variety, may become essentially normal (unpublished data of Merritt and Lennox, cited by Lennox, 1940). Apparently it is possible to relieve major seizures without improving the cerebral dysrhythmia.

Absorption, Fate and Excretion. Dilantin is satisfactorily absorbed from the intestinal tract. Only 2.5 to 10 per cent of the orally administered drug is recoverable in the feces and less than 0.1 per cent is found in the urine. The fate and distribution of dilantin in the tissues are unknown, but the drug apparently disappears from the body fairly promptly. Evidently several days are required to build up an effective level of dilantin in the brain because if phenobarbital is prematurely withdrawn when dilantin is started, epileptic attacks may become more frequent.

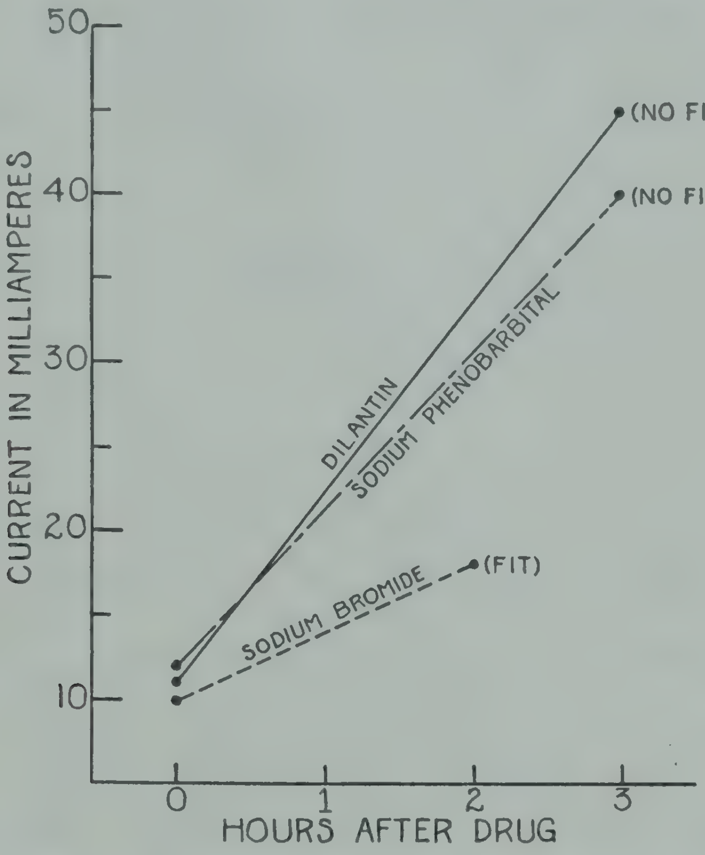


FIGURE 15. *The effect of anticonvulsant drugs on electrically-induced convulsions in cats.*

Dilantin, in doses producing minimal depression of spontaneous activity, increased the convulsive threshold to such an extent that a fit could not be produced with maximal currents. *Phenobarbital* exerted a similar anticonvulsant action only in doses which produced definite central depression. *Sodium bromide* was a poor anticonvulsant and, in doses causing marked depression, did not significantly increase the convulsive threshold. (After Merritt and Putnam, 1938. Courtesy of the *Archives of Neurology and Psychiatry.*)

Dosage. The initial dose of dilantin sodium for adults is 0.1 gram two or three times daily. This dose may be gradually increased if necessary until the optimal amount is reached. This optimal dose level must be determined by trial and error for each patient, and varies between 0.2 and 0.6 gram daily. The majority of adults tolerate 0.3 to 0.4 gram daily without toxic effects. Rarely does a patient tolerate a total daily dose larger than 0.6 gram. So critical is the effective anticonvulsant level of the drug that a reduction of the optimal dosage by 0.1 gram daily may result in the recurrence of attacks.

Children over six years of age may be started on a dose of 0.1 gram two or three times daily for one week, and this amount may then be increased to 0.4 gram daily if necessary. Small children (under four years of age) may be given 0.03 gram twice daily, the drug being mixed with cream to disguise the bitter taste and to lessen gastric irritation. If necessary, the number of doses may be increased cautiously to three or four per day.

If bromide or phenobarbital is being employed and it is desired to substitute dilantin, the former drugs should be discontinued gradually over a period of four to seven days while dilantin is being substituted. Otherwise, an increase in the number and severity of attacks may occur.

In some cases, dilantin can be administered in larger doses to coincide with the periods when seizures are likely to be most frequent. For example, nocturnal attacks may better be prevented by giving a greater portion of the total dose before bedtime, and women whose seizures occur especially at the time of the menstrual period may be given additional doses on the critical days. Adequate treatment must still be given in the interim.

Dilantin should be taken with at least half a glass of water with meals or just after meals in order to lessen the gastric distress frequently caused by the alkalinity of the drug. In occasional patients, nausea and vomiting may be severe. Relief may sometimes be obtained by giving one cc of dilute hydrochloric acid with each dose of dilantin.

Therapeutic Uses. The only known clinical use of dilantin at present is in the treatment of epilepsy, or in the diagnosis of so-called "epileptic-equivalents." Many reports have appeared testifying to the value of dilantin in epilepsy (*see* the review of Lennox [1940] on the drug therapy of epilepsy), but only those publications recording large series of cases can be analyzed here. Merritt and Putnam (1938) originally reported the following results: In 118 patients with grand mal, complete relief was obtained in 58 per cent and a marked reduction in the number of attacks occurred in 27 per cent. In 15 per cent, only a moderate degree of benefit or no improvement over the previous therapy with bromides or phenobarbital was noted. In 74 patients with petit mal, complete relief was obtained in 35 per cent, a marked reduction in the number of attacks in 49 per cent, and slight or no improvement over the prior status in 16 per cent. In six patients with psychomotor equivalent attacks, four were completely and two moderately relieved by dilantin. Subsequent reports by Merritt and Putnam (1939, 1940) on larger series of patients indicate the same general results. The drug appeared most effective in relieving psychic equivalent attacks, 12 of 19 patients experiencing complete relief. Of 20 other patients with psychic equivalents associated with grand mal, 12 were completely relieved. This is particularly stressed because of the inadequacy of bromides and phenobarbital in the management of this form of epilepsy. The over-all efficacy of dilantin in the 350 patients studied by Merritt and Putnam, most of whom had not been relieved by other drugs, surgical procedures or the ketogenic diet, may be appreciated from the fact that 79 per cent found dilantin more effective than any form of previous therapy.

In 129 epileptic children in whom Kimball (1939) used dilantin for more than three months, seizures were entirely controlled in 81 (62.7 per cent), definitely alleviated in 19 (14.7 per cent) and little or not at all benefited in 29 (22.5 per cent), a finding in substantial agreement with that of Merritt and Putnam. Kimball also reported that the mental state, memory, ability to concentrate, emotional stability and personality of his patients were greatly improved in comparison with the condition noted while on other therapy. In a later publication, Kimball and Horan (1939) reported their results with dilantin sodium therapy in a series of 220 children and young adults, most of whom had been using the drug for six months or longer and 50 of whom had been on dilantin for over a year. Seizures were entirely controlled in 55 per cent and partially controlled or modified in 20 per cent of the cases. In 25 per cent, there was little or no improvement.

Numerous other investigators have reported on the anticonvulsant properties of dilantin. These include Williams (1939), Blair and associates (1939), Frankel (1940), Butter (1940), Coope and Burrows (1940), Robinson and Osgood (1940), Fetterman (1940), and many others. The Report of the Council (1939) summarizes the results obtained in 595 patients treated by thirteen physicians and indicates that there is an unanimity of opinion regarding the fact that epilepsy is definitely improved as far as major seizures and psychic equivalent attacks are concerned. Of the 595 cases, dilantin was reported to be the most effective form of therapy in 404.

The combination of dilantin and phenobarbital appears to be especially beneficial in a number of patients in whom neither drug alone allows satisfactory relief of symptoms. The potentiation of effects obtained by this combination is often quite dramatic (Cohen and coworkers, 1940; Robinson and Osgood, 1940; Ebaugh, 1940). Petit mal may also be managed more satisfactorily by using both drugs together (Cobb, 1939). Promising results with dilantin in the treatment of epilepsy in psychotic patients likewise have been reported (Frost, 1939; Black, 1939).

Clinical Toxicity. Toxic reactions from dilantin occur in approximately 15 per cent of patients. These are usually mild, do not interfere with therapy and may often be relieved by proper adjustment of the dosage. Untoward effects are referable mainly to the central nervous system, gastro-intestinal tract, skin, and gums.

Central Nervous System. Reactions referable to the central nervous system include giddiness, ataxia, nervousness, tremors, nystagmus, head-nodding, diplopia, blurring of vision, ptosis, ocular pain, and slurring of speech. In some patients the drug may cause fatigue, apathy or confusion, drowsiness, and headache. In others insomnia, irritability, and quarrelsomeness may be noted. Rarely delusions, hallucinations and other psychotic manifestations may appear. In addition, there may be experienced difficulty in breathing and swallowing. These phenomena tend to appear between the third and tenth day of treatment and reduction in dosage usually brings prompt relief. If seizures are not held in abeyance by the smaller amounts of the drug, the dose of dilantin may be increased after a few days without necessarily initiating a recurrence of toxic effects. Untoward responses are more frequently observed if the dose level employed is above 0.5 gram daily.

Gastro-intestinal Tract. The gastric distress caused by the alkalinity of dilantin can usually be averted by taking the drug after meals or with dilute hydrochloric acid, as already stated. *Acute gastric upsets,* suggestive of chronic irritation, have also been reported (Kimball and Horan, 1939). The clinical picture is suggestive of the acute abdomen and is characterized by considerable epigastric pain and soreness, severe nausea and vomiting, and complete anorexia. Fever, leukocytosis and abdominal rigidity, however, are absent. The attack may last 48 hours and some patients have been operated upon for appendicitis. Apparently the gastric disturbance occurs only in those who have taken dilantin sodium for a long period of time and who have developed hyperplastic gums. Gastroscopic studies of one case revealed a recent submucosal hemorrhage and a second patient had a fatal hematemesis. In all, 62 gastro-intestinal attacks were observed in the series reported by Kimball and Horan.

Skin. Dermatitis is rather frequent after dilantin, occurring in five per cent of the 350 patients reported by Merritt and Putnam (1939), but the condition is rarely serious. The incidence of morbilliform rash in the 220 patients reported by Kimball and Horan (1939) was 10 per cent. The cutaneous eruptions due to dilantin may be erythematous, scarlatiniform or morbilliform in character, usually appear about the tenth day (seventh to fifteenth) of treatment, are often accompanied by fever, leukocytosis and occasionally by bronchial irritation, and are most often seen in children and young adults. The syndrome is reminiscent of the drug fever noted after sulfanilamide and resembles in many respects that caused by nirvanol. The rash disappears in all patients, however, regardless of whether dilantin is continued. Serious forms of dermatitis are evidently quite rare. Merritt and Putnam (1938) reported an instance of exfoliative dermatitis appearing 40 days after therapy was started and disappearing rapidly upon immediate discontinuance of the drug. They also recorded one patient in whom there occurred purpuric lesions confined to the buttocks and unaccompanied by constitutional symptoms or hematological abnormalities. The lesions cleared uneventfully, despite continuance of dilantin.

Hyperplasia of the Gums. An interesting and peculiar reaction which has been noted accompanying dilantin therapy is the development of *hyperplasia of the gums.* This occurs almost exclusively in children or young adults. The incidence of the reaction evidently varies considerably in different series. Hyperplasia of the gums was noted in 68 of 119 epileptic children receiving dilantin and examined by Kimball (1939), in 112 of the 220 patients reported by Kimball and Horan (1939), and in 30 of the 48 cases reported by Frankel (1940). The degree of gingival hyperplasia varies considerably and could be considered advanced in approximately one-quarter of individuals showing the reaction. The tissue change may appear within the first few months of therapy in some individuals, whereas in others it may not develop despite prolonged medication with dilantin. The incidence of gingival hyperplasia reported by Merritt and Putnam (1939) is considerably lower than those already cited. Only six per cent of their 350 patients receiving dilantin for periods up to two years developed the tissue change.

Soreness of the mouth and tender gums may appear from two to four weeks after starting dilantin and may precede the hyperplasia of the gums. Occasionally sponginess, bleeding on pressure and gingivitis may accompany the tissue overgrowth, but these features are mild or absent if oral hygiene is good. The condition does not cause the patient inconvenience, and dilantin need not be discontinued. Biopsy of the hypertrophic gum tissue in two patients (Kimball and Horan) showed a marked proliferation of the mucous membrane and connective tissue, suggesting chronic irritation.

The suggestion has been made that the hyperplasia is related to low vitamin C levels in the blood, but there is little evidence to substantiate the belief that the anomaly is in any way associated with scurvy or abnormal vitamin C metabolism. Indeed, experiments on animals do not indicate that dilantin influences the utilization of ascorbic acid (Report of the Council, 1939); and Gruhzit (1939) has shown that a vitamin C deficiency is not produced by the drug.

Miscellaneous Reactions. Hirsutism, especially in adolescent girls, has been reported to occur in rare instances. Swelling of the face has also been noted. The blood of some patients on dilantin therapy may show a slight leukocytosis and occasionally a mild eosinophilia.

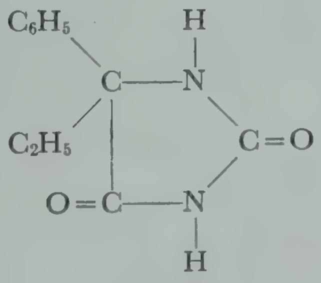
Status. Treatment with dilantin appears to be at least as effective in epilepsy as therapy with bromide, phenobarbital, or the ketogenic diet. That dilantin may prove superior to these measures is indicated by the fact that many of the patients reported to respond favorably to dilantin therapy had failed to respond to other measures. A distinct advantage of dilantin therapy is that the sedative effect of bromides and phenobarbital is avoided. Also noteworthy is the striking improvement in patients with seizures of the psychomotor (psychic equivalent) type, a form of epilepsy which is not often improved and which might even be aggravated by bromides or phenobarbital. Least promising results are obtained with dilantin in cases of petit mal in which there is transient loss of consciousness without muscle movement, and most promising results are recorded in grand mal in which dilantin is probably superior to phenobarbital. The drug may also be employed as a diagnostic test in questionable cases of so-called "epileptic equivalent." Finally, the mentality of many patients becomes clearer, either as a result of fewer seizures, or due to an effect of dilantin on the basic cerebral dysrhythmia characterizing epilepsy.

More work and experience are required to determine the toxic potentialities of dilantin, especially in regard to the cause and significance of the gingival hyperplasia and gastric episodes. At present, however, many thousands of patients have been treated continuously with the drug for periods ranging from several months to over three years with only occasional serious mishap, and scores of favorable clinical reports have been published. This in itself does not offer assurance that chronic medication with dilantin is innocuous and therefore patients receiving the chemical should be kept under close medical surveillance and impressed with the necessity of continuing under observation.

Dilantin must be placed in the same category as nirvanol, the toxic properties of which have long been known. Although dilantin has a greater margin of safety in respect to the fatal dose than bromides or phenobarbital, it causes more toxic reactions of a mild degree when used therapeutically. For the present it may be safest to restrict the administration of dilantin to those epileptic patients who fail to respond satisfactorily to better known methods of therapy (Council Report, 1939). The appearance of purpura or serious dermatitis should call for immediate discontinuance of dilantin, and an exfoliating eruption demands that the drug be withdrawn permanently. If drug rash or drug fever occurs in a mild form, dilantin may be cautiously resumed after a rest period. Certainly all the contraindications to dilantin are not yet known. Nor has it been determined whether patients become refractory to the drug after a long period of satisfactory response.

NIRVANOL

Nirvanol (phenyl-ethyl-hydantoin) is chemically allied to the barbiturates and was introduced into medicine as a sedative and soporific. Its chemical structure is as follows:



Nirvanol

Interest in nirvanol lies in the fact that at one time it enjoyed some favor in the therapy of *chorea* in children, and that it is closely related to dilantin, a drug of value in epilepsy. The use of nirvanol in chorea was discovered by accident when it was noted that the drug, given for sedation, arrested choreiform movements. It is now known that the action is not specific and depends upon toxic effects. Although nirvanol is still used, it has never gained much favor in the United States.

Nirvanol produces what has been termed the "nirvanol reaction" or "nirvanol sickness." Within one to two weeks after the oral administration of daily doses of 0.3 gram, a morbilliform rash and fever appear. The maculopapular eruption spreads from the trunk to the limbs and disappears in from four to five days. The temperature may reach 104 F. or higher. Few other symptoms are noted in most cases except that some children develop cervical adenitis, conjunctivitis and pharyngitis. The changes in the blood are quite interesting. Eosinophilia is the most striking and constant feature. There also occurs a leukopenia with a relative lymphocytosis and monocytosis. Occasionally, agranulocytic changes have been observed.

In the treatment of chorea, nirvanol is given with the object of producing the typical pyrexial, hematological and cutaneous reactions, because otherwise beneficial results are not observed. The maximal dose is 0.3 gram daily in divided doses for not over two weeks, and medication should cease as soon as rash or fever develops. It is claimed that the more marked the reaction, the greater is the improvement. It is interesting that, should a subsequent course of the drug be given, the temperature rise and rash are not noted, but only eosinophilia appears. A third course may not even elicit eosinophilia.

Status. Nirvanol is not an official drug and is not included in N.N.R. It should not be employed either as a sedative or for chorea. The benefit noted in some cases of chorea apparently depends on the fever, and safer methods of fever therapy are available for choreic children. The disease is characterized by marked fluctuations in its severity and by spontaneous remissions. It would thus be unwise to conclude either that nirvanol is a specific or that it has benefited all the cases which improve while under treatment with it. Similar remission has been noted after a toxic reaction of fever and rash secondary to the administration of phenobarbital for sedation. Finally, nirvanol is dangerous in that it may cause severe skin reactions of an exfoliative type, accompanied by cyanotic swelling of the eyelids and face, and inflammation of the tonsils, pharynx, gums and conjunctiva. The liver and kidneys are also occasionally involved, and bronchopneumonia and agranulocytosis may occur.

CHAPTER 11

HYPNOTICS AND SEDATIVES

III. CHLORAL HYDRATE, PARALDEHYDE AND MISCELLANEOUS AGENTS

CHLORAL HYDRATE

Historical. Chloral hydrate, first made by Liebig in 1832, was introduced into medicine by Liebrich in 1869, at a time when cannabis, alcohol and morphine were the main central depressants. Liebrich wrongly believed that chloral hydrate would be changed to chloroform in the body and in this manner exert its hypnotic action. Chloral hydrate is the oldest member of the hypnotic group, and clinical studies show that it is still one of the cheapest and best.

Chemistry. Chloral hydrate is a chlorinated derivative of ethyl alcohol. There is an entire series of chlorals, but the one of greatest medicinal value is chloral hydrate. When chlorine acts as an oxidizing agent on alcohol, chloral (CCl_3CHO), an oily liquid, is formed. Hydration of *chloral* yields *chloral hydrate,* $CCl_3 \cdot CH(OH)_2$, a crystalline substance.

Pharmacological Actions

Local. Chloral hydrate is quite irritating to the empty stomach and therefore must be given well diluted or it will cause nausea and vomiting. The irritating property of the drug is the basis for its use in rubefacient liniments, such as *Camphorated Chloral,* N.F., which is a liquid containing equal parts of camphor and chloral hydrate. Cutaneous erythema, warmth and slight local anesthesia result from its surface application; but, if larger amounts or longer contact are employed, pain, vesiculation and necrosis of the skin occur. Chloral hydrate is also used in conjunction with phenyl salicylate in the prophylaxis of epidermophytosis of the feet, and with salicylic acid in the treatment of warts.

Systemic Actions. Chloral hydrate has the typical action of the methane series of anesthetics. It is never used for general anesthesia, however, because the margin of safety is too narrow with the large doses required for this purpose. The main use of chloral hydrate is as a sedative and soporific. Its analgesic powers are weak, as is the case with all the hypnotics.

In ordinary doses of one or two grams, chloral hydrate causes sedation, ordinarily without preliminary excitement, in from 10 to 15 minutes. Sleep occurs within the hour. It is a quiet and deep sleep, often accompanied by dreams, and lasts from five to eight hours; but sleep is not so deep that the patient cannot be readily aroused. For all these reasons, it has been called "physiological sleep."

Generally there are no after-effects and no "hangover." Reflexes are not greatly depressed and therefore chloral hydrate is not the best anticonvulsant. Rarely, therapeutic doses of chloral hydrate may cause excitement or delirium, especially in the presence of pain, and the patient may appear to be inebriated.

Doses somewhat larger than the therapeutic cause deeper and longer sleep and also obtund pain. With very large doses, six grams or over, it is possible to obtain complete anesthesia, but this is dangerous because such amounts approach too closely those capable of causing respiratory paralysis.

Blood Pressure and Respiration. These functions are little more depressed by chloral hydrate than by ordinary sleep. The blood pressure may fall slightly from muscular inactivity and peripheral vasodilatation as a result of mild central vasomotor depression. The respirations are somewhat slower than in normal sleep.

Heart. The belief that chloral hydrate depresses the heart is largely erroneous. While it is true that the drug may cause cardiac depression, as can many of the halogenated hydrocarbons, there is no good clinical evidence of any deleterious effect on the heart from the continued use of therapeutic doses (Alstead, 1936). Untoward cardiac effects occur only with toxic doses in patients with heart disease.

Absorption, Fate and Excretion. Chloral hydrate is absorbed readily from the gastro-intestinal tract. It has long been believed that chloral hydrate is reduced in the body to trichlorethylalcohol, CCl_3CH_2OH, in itself a potent hypnotic. This alcohol is then combined, principally in the liver, with glycuronic acid to form trichlorethylglycuronic (urochloralic) acid which is not hypnotic. Detoxification of chloral hydrate occurs over a period lasting several hours.

The fate of chloral hydrate has been called into question by Lehman and Knoefel (1938) who found that trichlorethylalcohol is more powerfully hypnotic than chloral hydrate and that the latter's potency and duration of action cannot easily be explained on the basis of reduction of the hydrated aldehyde to the alcohol. Furthermore, when chloral hydrate is given, little urochloralic acid is recovered from the urine, whereas more appears after trichlorethylalcohol.

The pharmacological actions of *trichlorethylalcohol* ($CCl_3 \cdot CH_2OH$) have been studied in comparison with tribromethanol by Lehman and Knoefel (1939), and the results of animal experiments suggest that the drug may prove of clinical value as a basal anesthetic.

The urine of patients receiving full doses of chloral hydrate may give a false positive test for sugar. The elimination of chloral hydrate in the urine has been proposed as a test for liver function (Mukerji and Ghose, 1939).

Poisoning. *Acute.* The toxic dose of chloral hydrate for adults is approximately 10 grams, although death has been reported to occur from as little as four grams. On the other hand, a single dose of 30 grams was not fatal to one patient, nor was 20 grams given daily for three days to another. Nevertheless, care should be exercised in giving more than two grams of the drug as a single dose. The usual features of poisoning by chloral hydrate are deep stupor, marked vasodilatation, low blood pressure, fall in body temperature, slow respiration and cyanosis. Gastric irritation may result in initial vomiting. Occasionally delirium occurs, or prompt collapse. Pin-point pupils may be seen, as with morphine poisoning. Icterus due to liver damage and albuminuria from renal irritation may appear if the patient survives. Death results from respiratory depression, usually within five to 10 hours. In patients with impaired hearts, cardiac collapse may cause death.

Acute poisoning may also occur from the combination of liquid chloral and alcohol, so-called "knock-out drops" ("Mickey Finn"). Apparently, such a mixture is quite potent and rapidly depressant. It was long believed that chloral alcoholate was formed by the combination of alcohol and chloral and that this compound accounted for the enhanced depressant properties of the mixture. However, Adams (1940) was unable to find any data in support of the belief that chloral alcoholate is more toxic than chloral hydrate, and his experiments in rats even indicate that the alcoholate is slightly less hypnotic and less toxic than the hydrate.

Treatment of acute poisoning consists in gastric lavage, warmth, stimulants for the respiration and blood pressure, artificial respiration if needed, and in general the same measures employed in barbiturate poisoning. In addition, hypertonic glucose solution should be given intravenously not only to combat shock, maintain blood pressure and promote diuresis but also to protect the liver against damage.

Chronic Poisoning. This occurs especially in persons with the "*chloral habit,*" common formerly but rare today. The continued use of chloral hydrate leads to habituation and a slight degree of tolerance. Chloral hydrate habitués often rapidly develop an impaired mechanism for the detoxification of the drug and sudden death may occur from what formerly was termed a "break in tolerance," which is due either to an overdose or to the failure of the detoxification mechanism as a result of liver damage. Parenchymatous renal injury may also occur. The chloral habitué bears many clinical resemblances to the chronic alcoholic addict, but usually has a more severe gastritis. Skin manifestations are sometmes seen and may be erythematous, urticarial or even purpuric.

Treatment consists of withdrawal of the drug, correcting the basic cause of the habituation, and rehabilitating the patient. It is essentially similar to that for alcoholic addiction. Sudden withdrawal may occasionally produce a clinical picture similar to delirium tremens.

Preparations and Doses. *Chloral Hydrate,* U.S.P., B.P., is a colorless, transparent crystalline substance with an aromatic, penetrating, acrid odor and a slightly bitter, pungent taste. It is very soluble in water, alcohol and oils and can therefore be dispensed in a number of ways, but it has many incompatibilities. The drug forms a liquid when mixed with many substances, especially camphor and menthol. It should not be given in any strongly *alcoholic* vehicle because chloral alcoholate may be formed. The N.F. contains a preparation consisting of chloral hydrate (25 per cent), potassium bromide (25 per cent) and extracts of hyoscyamus and cannabis in distilled water, known as *Elixir of Bromide and Chloral.*

The usual adult hypnotic dose of chloral hydrate is 0.5 to 1.0 gram, but two grams may be given if necessary. Larger amounts are used in cases of mania or delirium, but these should be given with care. In prescribing chloral hydrate for oral use, one should guard against gastric irritation. The drug is too hygroscopic to be prescribed in capsules and must be given in solution. The syrups of orange and citric acid mask the taste fairly well, and solutions of the drug in such vehicles should be taken well diluted with water or milk. Chloral hydrate is too irritant to be given hypodermically, but can be given rectally in solution in olive oil or some other bland fixed oil.

Uses. The *sedative and soporific uses* of chloral hydrate are similar to those of the barbiturates and paraldehyde. The poor analgesic properties of the drug do not permit its effective use alone in the presence of pain. Chloral hydrate is frequently used in patients undergoing morphine or alcohol withdrawal, and in delirium tremens. At one time, it was also considered particularly valuable in the management of eclampsia (Stroganoff treatment) for which purpose chloral hydrate was administered rectally at intervals. If convulsions are actually present, the barbiturates given intravenously are to be preferred.

Chloral hydrate is *contraindicated* in patients with marked hepatic or renal impairment and severe cardiac disease. If gastritis is present, the drug should not be given orally but may be administered in olive oil as a retention enema.

Chloral hydrate is unfortunately neglected today. The ease with which the barbiturates are dispensed and the prominence given them in medical literature and in advertising have caused the physician to lose sight of the fact that chloral hydrate is still one of the cheapest and most effective hypnotics (Grabfield, 1931, 1936).

OTHER CHLORAL HYNOPTICS

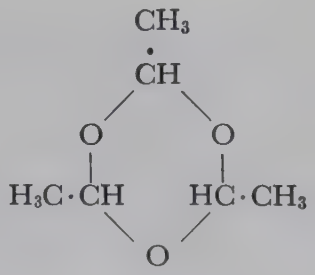
Butylchloral Hydrate, N.N.R., $CH_3CHCl \cdot CCl_2CH(OH)_2$, is a crystalline white powder with a pungent odor and acrid taste and soluble 1:50 in water and 1:1 in alcohol. It has much the same hypnotic properties as chloral hydrate and is said to possess some analgesic value in addition. The adult dose is 0.3 to 1.0 gram and the drug may be given orally in capsules.

Chlorobutanol (*Chlorbutol*), U.S.P., B.P., $Cl_3C.C(CH_3)_2.OH$, has the advantage over chloral hydrate of not causing gastric irritation. In fact, it has a local anesthetic action and may be used as an anesthetic dusting powder (one to five per cent) or ointment (10 per cent), or may be taken orally to allay vomiting due to gastritis. The drug consists of colorless crystals with a somewhat camphoraceous odor and taste and is soluble in water 1:125 and in alcohol 1:1. The hypnotic oral dose for adults is 0.3 to 1.0 gram, given as tablets or in capsules. The drug is also serviceable as a preservative in solutions of epinephrine, posterior pituitary, etc.

PARALDEHYDE

Historical. Paraldehyde was introduced into medicine by Cervello in 1882. It is still considered a very efficient hypnotic, but is not used as frequently as it deserves to be.

Chemistry. Paraldehyde (paracetaldehyde) is a polymer of acetaldehyde, in which three molecules of the latter are joined in a cyclic structure. The suggested formula is as follows:



Paraldehyde

Paraldehyde is a colorless transparent liquid which has a strong, characteristic pungent odor and a burning, disagreeable taste. It is soluble in water only to the extent of one part in eight, but is freely miscible with alcohol and oils. Paraldehyde remains sterile and requires no preliminary treatment before parenteral use. It is easily inflammable.

Pharmacological Actions. The action of paraldehyde on the central nervous system is similar to that of chloral hydrate. With the ordinary hypnotic dose of four to eight cc, sleep ensues in 10 to 15 minutes, more promptly than with any other sedative. Therefore, the patient should be in bed and prepared to retire when the drug is taken. The sleep produced is quite normal and without after-effects. Paraldehyde rarely causes preliminary symptoms of excitement. The soporific effects are not as potent or certain as those of chloral hydrate, but therapeutic or even larger doses do not depress the respiration or circulation. Paraldehyde is not analgesic, although large doses cause sleep despite the presence of pain.

Absorption and Excretion. Paraldehyde is absorbed rapidly from the gastrointestinal tract, and also from intramuscular sites of injection. The characteristic odor of paraldehyde, similar to that of fusel oil, appears on the breath within a few minutes after ingestion of the drug. The fate of paraldehyde in the body is unknown. In dogs, it apparently is oxidized in large part (Defandorf, 1939). The experiments of Levine, Gilbert and Bodansky (1939) suggest that the liver is an important seat for the destruction of paraldehyde. Following liver injury induced in dogs by chloroform, administration of paraldehyde resulted in prolonged hypnotic effects and elevated blood paraldehyde curves, indicating decreased ability of the liver to detoxify the compound. That fraction of the ingested paraldehyde which escapes destruction in the tissues is excreted unchanged largely by the lungs, and in smaller part by the kidneys. In some species (rat), paraldehyde is quantitatively excreted by the lungs. Paraldehyde is not contraindicated in patients with renal disease as is chloral hydrate for which the kidney is an obligatory channel of excretion.

Toxicity. The acute toxicity of paraldehyde is low, and the drug possesses a wide margin of safety. Very large doses cause only prolonged unconsciousness, fatalities being quite rare (Kotz, Roth and Ryon, 1938). As much as 104 cc has been taken in a single dose; the patient recovered after a 32-hour sleep; 120 cc were mistakenly given rectally to a woman in labor without fatality (Hanson, 1937). On the other hand, a dose of 31 cc given rectally has caused death. Impaired hepatic function may play a rôle in the occasional case of hypersusceptibility to paraldehyde. The symptoms and treatment of acute poisoning are the same as those for chloral hydrate. The diagnosis is facilitated by the characteristic odor of the breath.

Tolerance and Habituation. Some degree of tolerance to paraldehyde may occur with its continued use. Habituation develops rather infrequently, due mainly to the fairly disagreeable odor and taste of the drug. The paraldehyde habitué resembles the alcoholic addict, may even experience delirium tremens, and is treated in the same manner.

Preparations and Dose. *Paraldehyde,* U.S.P., B.P., is usually given orally in doses of three to eight cc. One may increase this to 10 or 15 cc if necessary. The drug is difficult to dispense, due to its poor solubility in water and unpleasant taste. Syrups of orange and cinnamon may serve as vehicles, or paraldehyde may be taken in milk, fruit juices or wine. It can also be given in iced water or tea, or on cracked ice. Paraldehyde can be dispensed in gelatin capsules, but this, as a rule, is too troublesome and expensive. A convenient way, especially if the patient cannot cooperate or needs large doses, is to administer the drug rectally as a small retention enema. For this purpose, 10 to 20 cc may be mixed with one or two parts of olive oil in order to avoid the discomfort of rectal irritation, or one cc of benzyl alcohol may be added to the paraldehyde for the same purpose.

Status. Paraldehyde is one of the best and least toxic hypnotics. Despite the odor and the difficulty of dispensing it in a pleasant form, paraldehyde deserves a wider popularity than it enjoys at present. Many physicians feel that ease of administration of hypnotic drugs, as is the case with the barbiturates, encourages their misuse.

Uses. The indications for the soporific use of paraldehyde are the same as for other hypnotic agents. Due to its odor, paraldehyde cannot often be employed for the purpose of mild sedation in ambulatory cases. In delirium tremens, paraldehyde is often administered to quiet the patient and produce sleep, for which very large doses (15 to 30 cc or more) are needed.

Paraldehyde may be used in emergency for strychnine or cocaine convulsions, if a soluble barbiturate is not available. It is given slowly intravenously, usually diluted with several volumes of sterile physiological sodium chloride solution. When paraldehyde is given intravenously, central depression may be preceded by a few seconds of excitement or coughing. The intravenous route is not without danger, for the drug may very occasionally cause circulatory collapse or pulmonary edema, and should be injected only if absolutely necessary. The dose by vein is four or five cc, but the injection should be stopped as soon as the desired degree of depression is obtained. Another parenteral use for paraldehyde has been for an occasional patient with acute coronary thrombosis who fails to obtain relief from pain by repeated injections of morphine sulfate. In such an instance, paraldehyde has been given by intramuscular injection in doses of five to eight cc or by intravenous injection in smaller amounts. Pain occurs from intramuscular injection, but it rapidly disappears with the onset of sleep.

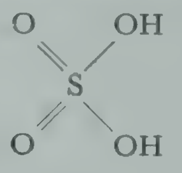
Paraldehyde has also been employed by rectal administration for obstetrical analgesia and amnesia, usually in combination with other drugs such as barbiturates and scopolamine (Kotz and Kaufman, 1939). This type of anesthesia should be employed only by those thoroughly familiar with the technic and dangers of the use of paraldehyde as a basal anesthetic.

Contraindications and Disadvantages. In bronchopulmonary disease, paraldehyde at times may be contraindicated because of the excretion of the drug by the lungs. Hepatic insufficiency also may be a contraindication to the use of paraldehyde (Levine and coworkers, 1939) inasmuch as approximately 80 per cent of the drug is destroyed in the body, presumably by the liver. The amount of paraldehyde excreted by the lungs increases in the face of hepatic insufficiency. In patients with gastro-enteritis, especially if ulceration is present, paraldehyde may cause considerable irritation. One of the chief disadvantages of paraldehyde arises from the odor it imparts to the exhaled air for as long as 24 hours. The entire room may be "perfumed" by a patient who has received the drug. The patient, however, is unaware of the odor. One who must go about his daily affairs in contact with others may not thank the physician who has given him a night's sleep at the expense of the following day's embarrassment. A second disadvantage is the unpleasant taste of paraldehyde and the irritation of the throat and gastric mucosa which may ensue if the drug is not given well diluted in a proper vehicle. Finally, paraldehyde is quite toxic when combined with morphine, but such a combination can readily be avoided.

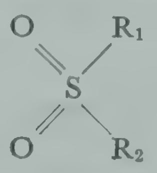
SULFONMETHANE (SULFONAL)

Historical. The ethyl sulfones were first prepared in 1885 and introduced into therapeutics by Baumann and Kast in 1888. For many years they represented the hypnotics most frequently used, but now they have been almost completely discarded.

Chemistry. The sulfones are sulfuric acid derivatives, as follows:

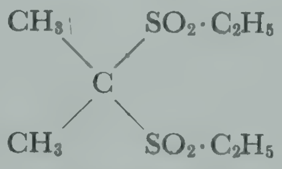


Sulfuric Acid



Sulfone

The sulfones used in therapeutics are more properly viewed as derivatives of methane. For example, sulfonmethane itself is diethylsulfone dimethylmethane, with the following structure:



Sulfonmethane

Sulfonmethane is a nearly tasteless, colorless, crystalline powder, which is almost insoluble in water (1:450), but soluble in boiling water to the extent of 1:15. The hypnotic action of sulfonmethane is largely resident in the ethyl radicals, and is increased by substituting one or both methyl groups with ethyl, to form sulfonethylmethane and sulfondiethylmethane, respectively.

Pharmacological Actions. Sulfonmethane is a fairly powerful hypnotic, but a weak analgesic. Sulfonmethane is absorbed very slowly from the intestinal tract and hence its effects are tardy in appearing. In fact, sedation or sleep may not appear for from two to five hours or more after administration. One is therefore at a loss to predict the hypnotic effects or to know exactly when to give the drug in relation to bedtime. Sleep, once induced, continues for six to eight hours.

Sulfonmethane is also slowly excreted, and after-depression upon awakening is marked. This consists of lassitude, dizziness, and mental depression and may be so pronounced that the patient is often inclined to sleep on the night of the second day without necessity for hypnotic medication.

Excretion. Excretion of sulfonmethane occurs slowly in the urine. Some of the chemical is also eliminated through the intestines, and a small amount by way of the skin. The drug is excreted partly unchanged, and partly as ethylsulfonic acid which has no depressant action. A period of several days is required for the complete elimination of a single therapeutic dose.

Toxicology. A single therapeutic dose of sulfonmethane affects neither circulation nor respiration, and the margin of safety is ample. However, this holds true only for discontinuous administration. Because of the slow rate of excretion of sulfonmethane, cumulative toxic effects and serious poisoning occur if administration is continued for any length of time. The drug is therefore obviously unsuitable for repeated or chronic use.

Acute poisoning results from overdosage, and is characterized by deep sleep and gradual failure of the respiration and circulation. Death or recovery occurs after prolonged coma. A single dose of from five to 30 grams occasionally may cause acute poisoning, but recovery has followed the ingestion of 100 grams.

Chronic poisoning occurs only after several weeks of daily therapeutic doses of sulfonmethane. The patient slowly develops symptoms referable to the nervous system—paresis, ataxia, mental depression, polyneuritis, muscle cramps; symptoms referable to the gastrointestinal tract—vomiting, periumbilical pains, tympanites, diarrhea or constipation; and urinary changes with the presence in the urine of methemoglobin, hematoporphyrin, casts and red blood cells. Hematoporphyrin, when present, is characteristic of chronic poisoning by sulfonmethane. It imparts a dark cherry-red color to the urine which is black in reflected light. Cutaneous eruptions may occur, and fatty degeneration of the liver and acute glomerulonephritis sometimes result. The blood may contain detectable amounts of sulfhemoglobin, methemoglobin and hematoporphyrin. Death occurs several weeks after the appearance of symptoms, and is preceded by terminal anuria, collapse and coma. Recovery ensues slowly if the drug is stopped when the degree of poisoning is still mild; but if the urinary changes described have already appeared, the prognosis is grave.

Preparations and Doses. *Sulfonmethane* (Sulfonal) N.F., B.P., is given in the usual soporific dose of 0.75 to 1.0 gram, but as much as 2.0 grams may be taken at once. The drug can be dispensed in capsules, as a powder, or in hot milk or other hot drinks, and should be ingested at least three to four hours before retiring. Because of the danger of cumulative toxic effects, daily doses should not be prescribed continuously for more than one week at a time. Sulfonmethane is rarely prescribed.

SULFONETHYLMETHANE (TRIONAL)

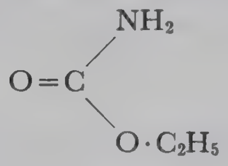
Sulfonethylmethane is chemically similar to sulfonmethane, an ethyl group in the former compound replacing one of the methyl radicals of the latter. This enhances the hypnotic potency. *Sulfonethylmethane* is official in the U.S.P. It is a colorless, odorless, bitter crystalline powder which is soluble in alcohol, but only slightly soluble in water (1:200). Sulfonethylmethane, however, is more soluble and more quickly absorbed than sulfonmethane. Nevertheless, it requires from one-half to one hour or longer to produce sedation or sleep. The drug has the uses and dangers of sulfonmethane, but is to be preferred to the latter. The single soporific dose is 0.75 to 1.3 gram, best administered in hot milk or other hot drinks. The drug is rarely used.

SULFONDIETHYLMETHANE (TETRONAL)

Sulfondiethylmethane differs from sulfonmethane in that both methyl groups in the latter compound are replaced by ethyl radicals. It is therefore considerably more powerful as an hypnotic than is sulfonmethane; but it is even less soluble. Consequently the drug is much too slow in its onset of action to be of clinical use. One is never certain in giving sulfondiethylmethane whether its effects will be manifest on that day or the day following.

URETHANE

Urethane (Ethyl Carbamate), N.F., has the following structural formula:



Urethane

It is closely related chemically to urea and carbromal and consists of colorless crystals which are very soluble in water and alcohol. The *hypnotic action* of urethane in man is feeble but it is rapid and potent in animals. Urethane is thus used chiefly as a laboratory anesthetic. It is oxidized in the body to carbon dioxide and urea and is non-toxic in therapeutic doses. The adult hypnotic dose is two to four grams, but the drug is seldom used. Urethane is combined with quinine hydrochloride as a *sclerosing solution* for the injection treatment of varicose veins (page 912).

Various urethane derivatives have from time to time been employed as hypnotics, such as *aponal* and *hedonal*. The latter, for example, is obtained by substituting the radical methyl propyl carbinol for the ethyl group of urethane, to yield the following structure: $NH_2 \cdot CO \cdot O \cdot CH(CH_3)CH_2CH_2CH_3$. Hedonal is more depressant and more toxic than urethane and its use is not advised.

BULBOCAPNINE

This interesting alkaloid is discussed here not because it is used clinically as a central depressant, but rather for the reason that its main action, depression of certain functions of the brain stem, permits no other classification. *Bulbocapnine* is derived from tubers of the *Corydalis bulbosa* or *cava* plant, commonly known as "Dutchman's breeches." Chemically, the alkaloid bears a striking resemblance to apomorphine. Two interesting points arise in this connection. First, the slight difference in chemical structure of bulbocapnine divests it of the emetic action so characteristic of apomorphine. Second, some species of *Corydalis* are closely related to the poppy family and contain chemical substances which have not been investigated. As long ago as 1526, bulbocapnine was recommended for diseases of the head and nerves, and for trembling of the hands, and it has been used sporadically for tremor up to the present time. The history of the drug has been reviewed by de Jong and Schaltenbrand (1924).

Actions. The administration of bulbocapnine to animals results in a peculiar state of catalepsy. This was first described in cats by Peters in 1904, and since then has been demonstrated for nearly all species studied. When a dose of 40 mgm per kg is injected subcutaneously into a cat, there occurs in about ten minutes a "fixed posture" which is maintained for several hours. Voluntary motion is absent, and a peculiar plastic rigidity ensues which allows the animal to be bent like a lead pipe, and placed in many bizarre positions. Some degree of sedation and lethargy is also noted, especially in rabbits and guinea pigs. Recovery with no after-effects is complete within 18 hours. When larger doses are given, tonic and clonic convulsions appear, and death may follow.

Electromyograms show the skeletal muscles to be entirely normal during the rigid state and the site of action is therefore believed to be central. Whether the phenomenon of plasticity is due to simultaneous contraction of antagonistic muscles or to some other disturbance of reciprocal innervation is not clear. The effect of bulbocapnine on the grasp reflex and hanging response in monkeys and the bearing of this on flexor tone and catalepsy were investigated by Richter and Paterson (1931). Cocaine counteracts the catatonia, especially in monkeys (Buchman and Richter, 1933), and scopolamine enhances it. Other pharmacological actions of bulbocapnine thus far described are of no immediate interest.

Use and Status. Bulbocapnine has greater academic than clinical importance. It has sporadically been tried for the control of tremor in paralysis agitans and Parkinson's disease with varying success. The drug seems to be less effective than scopolamine and has not gained wide favor. It has also been employed in encephalitis and chorea but the reports of success are highly questionable. The dose for an adult human being is 200 mgm given orally. A dose of 500 mgm may cause moderate drowsiness. No cumulative or toxic effects appear even after several months of medication. Bulbocapnine has remained a pharmacological curiosity and is employed chiefly as a means of studying cataleptoid states in animals and to immobilize the latter for other purposes.

CANNABIS

History and Source. Cannabis is obtained from the flowering tops of hemp plants. These grow wild in many parts of the world and are indigenous to the United States. The cultivation of hemp plants for commercial purposes is under the regulatory control of the Federal Government. Cannabis is now listed separately as a narcotic.*

Cannabis is a very ancient drug, and was used in the Orient before the time of written history. It is described in a Chinese herbal of the fifth century B.C. Other names for it include *hashish, marihuana* and *bhang*. The term *hashishan* is Arabic for herb-eaters. There is some dispute as to whether the English word "assassin" is derived from "hashish." The term "marihuana" is said to be a corruption of the Portuguese word "maraguango," meaning intoxicant. The drug is habitually used for its psychic effects by millions of people in all parts of the world; preparations of it are smoked, chewed or drunk.

Hemp has considerable commercial value. The fibers are used for twine, rope, bags and clothing. The seeds yield an oil which is employed in paints, varnishes and linoleum. The seeds themselves are even eaten as a gruel in the Orient in times of food shortage.

Active Principle. The source of the official U.S.P. *Cannabis* is from *Cannabis sativa*. Little is known concerning the active principle of cannabis except that it is not an alkaloid. A red syrupy oil called *cannabinol* obtained by vacuum distillation has been found to contain a highly active substance. Cannabinol is soluble in alcohol but not in water.

---

* Narcotic-Internal Revenue Regulations Relating to the Importation, Manufacture, Production, Compounding, Sale, Dealing In, Dispensing, Prescribing, Administering and Giving Away of Marihuana. U. S. Government Printing Office, Washington, D. C., 1937. Price, 10 cents

and is variously said to be a diterpene or dibenzopyran structure. It is excreted from the body through the kidneys in combination with glycuronic acid. Standardized preparations of cannabis are difficult to obtain and differ widely in their potency. Besides cannabis itself, which is the dried flowering plant top, the *Extract of Cannabis* (dose 15 mgm) and the *Fluidextract of Cannabis* (dose 0.1 cc) are official U.S.P. drugs. The chemistry of various fractions of cannabis has been reviewed in the monograph by Walton (1938).

Freshly extracted cannabis possesses a brilliant green color which results from its content of chlorophyll. This extract has been employed to color corn medicines green.

Actions of Cannabis. The effects of cannabis manifest themselves almost entirely on the central nervous system. The psychic changes brought about by the drug are particularly interesting and have formed the subject of many works of fiction. The actions have been studied by pharmacologists and psychiatrists alike. A particularly fascinating older description of the actions of cannabis is given by Wood who himself took an overdose and reported his experiences (Wood, 1869).

The central effects of the drug combine elements of excitation and depression, and vary with the personality of the individual, the route of administration, and the species and potency of the cannabis. The commonest method of using the drug in the United States is to smoke it in the form of cigarettes which are known as "reefers." These are shorter and thicker than the common cigarette, are wrapped in brown paper and are sold illicitly. The smoking of two to three reefers usually brings on the desired effect.

Soon after taking cannabis the subject finds himself in a dreamy state of partial consciousness in which his ideas are disconnected, uncontrollable and plentiful. At times, there is a feeling of extreme well-being, exaltation, excitement and inner joyousness. At other times, the subject may sink into a moody revery, or experience panic-states and fear of death. Ideas come in disrupted sequences, things long forgotten are remembered and others well known cannot be recalled, imagination runs riot, and perception is crowded and disturbed. Minutes seem to be hours, and seconds seem minutes. Even space may be broadened and near objects may appear far distant. The head often feels swollen and the extremities feel light and lengthened. Extremely vivid hallucinations are experienced; these are often very pleasant and may have sexual coloring. Illusions are also common, and the feeling of being a dual personality may occur. Behavior is impulsive, mood is elevated and random ideas are quickly translated into action in the motor field.

Delirium and mania can ensue, and violent acts have been committed under the influence of cannabis. Suicide, homicide and sexual assaults have been blamed on the use of the drug, but the evidence is not always of the most acceptable variety. Inasmuch as inhibitions are removed by cannabis and personality traits thereby exaggerated, the criminal is perhaps emboldened to do violence. The psychiatric and criminological aspects of the use of marihuana have been well reviewed by Bromberg (1939).

Central depression also results in anesthesia of the skin, and the modalities of pain and touch are especially obtunded. Hearing, however, may be intensified for some time. Large doses eventually produce sleep, but the psychological effects may persist upon awakening for 24 hours and longer. The drug is said to have some diuretic action.

Addiction and Habituation. Addiction to cannabis does not occur in the same sense as it does to morphine, but habituation develops. Discontinuance is therefore easier and does not entail the sequence of profound psychic and organic symptoms seen in morphine withdrawal (Bromberg, 1934, 1939; Yawger, 1938). Although cannabis may be considered a habit-forming drug in the sense that its devotees continue to take it to experience again and again the sensations and feelings which the drug produces, true addiction cannot be said to exist. Also, tolerance, so far as is known, does not develop. There are no recognizable lasting ill effects from the acute use of marihuana, and fatalities do not occur.

The prolonged use of the drug in psychopathic personalities may eventually result in mental deterioration, a fact known for centuries in Egypt and the Orient. Chronic dementia and deterioration, however, have not been reported from American clinics. Cannabis has also been considered as a breeder of crime in psychopathic individuals, a concept supported by the acts of violence presumably committed while under the acute toxic influence of the drug. However, from a study of 67 cases involving marihuana observed in the Psychiatric Clinic of the Court of General Sessions, New York County, Bromberg (1939) reported that no positive relation could be found between violent crime and use of the drug. No cases of murder or sexual crimes due to marihuana were established.

In many large cities there are clubs or dens where marihuana users congregate for smoking and mating. It is difficult to appraise the extent of the marihuana habit and the few reliable statistics available are at odds with the impression one gains from reading the newspaper headlines. The law enforcement agencies give the opinion that marihuana smoking is spreading among the younger age groups, especially high school students. Steps have been taken by the Federal Government to control the cultivation of hemp, but this is difficult because the plant grows wild in yards and by the roadside. The illicit sale of reefers is the source of the main supply of cannabis to the laity.

Uses. Cannabis has no rational or indispensable uses in modern medicine. While it was formerly employed empirically in migraine, insomnia, neuralgia and many other syndromes, it is now no longer prescribed.

CHAPTER 12

MORPHINE AND OTHER OPIUM ALKALOIDS

In 1680 Sydenham wrote, "Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium." This appraisal is still true today. If it were necessary to restrict the choice of drugs to a very few, the great majority of physicians would place the opium alkaloids, particularly morphine, at the head of the list. Morphine is unequalled as an analgesic and its indispensable employment in medicine and surgery is well defined.

History. The word "opium" is derived from the Greek word for juice, the drug being obtained from the juice of the poppy capsules; the term "codeine" comes from the Greek for poppy head. Thebaine, another natural alkaloid of opium, obtains its name from the Egyptian town of Thebes where a certain type of opium was produced. "Thebaicum" has survived as another name for opium.

The poppy plant is indigenous to Asia Minor. From there the use of opium spread to Greece. Although opium was used before history was recorded, the first undisputed reference to poppy juice is found in the writings of Theophrastus in the third century B.C. He called opium "meconion" and the synonym "meconium" has persisted to this day. Dioscorides in the first century A.D. was fully acquainted with the method for the collection and preparation of opium and his directions for preparing syrup of poppy, "dia-kodion," are essentially unchanged in modern pharmacopeias.

Arabian physicians were well versed in the uses of opium. The introduction of the drug to the Orient and China was accomplished by Arabian traders. The Chinese employed opium mainly for the control of dysenteries. The spread of the opium habit throughout China did not occur until the latter part of the eighteenth century when the Portuguese and later the English started to exploit the natives in this regard. The war against opium has continued ever since and at times has resulted in armed conflict.

By the middle of the sixteenth century, the uses of opium which are valid today were fairly well understood in Europe. Paracelsus called opium the "stone of immortality" and leaned heavily on its employment in his medical practice. To him is accredited the compounding of tincture of opium or "laudanum" which is an official preparation today. Von Helmont, a contemporary of Sydenham, was called Doctor Opiatus because he prescribed opium so frequently. Paregoric, another pharmacopeial mixture, dates from an elixir for asthma first prepared in the early eighteenth century by Le Mort, the chemistry professor at Leyden. The word paregoric comes from the Greek term for "soothing." Dover's powder is another opium-containing drug which has survived through the years. It is named for the famous English adventurer and physician, Thomas Dover, who introduced the powder as a sweating agent for gout in 1732. Dover is probably better remembered as the rescuer of Selkirk, characterized in fiction as Robinson Crusoe. The "brown mixture," opium and licorice, is named for its color and not its originator, Dr. Barton of Philadelphia (1814).

Until well into the 19th century the only opium preparations used medicinally were crude extracts. In 1805, a young German pharmacist in Hanover named Sertürner isolated and described morphine. This epochal finding went unnoticed until his later publication in 1816. Sertürner almost lost his life by experimenting with morphine on himself. The discovery of other alkaloids in opium quickly followed that of morphine and the use of pure alkaloids rather than crude preparations soon spread throughout the medical world. Codeine was isolated by Robiquet in 1832 and papaverine by Merck in 1848. One interested in the history of opium is referred to the interesting account given by Macht (1915).

Source and Composition of Opium. Opium is obtained from the milky exudate of the incised unripe seed capsules of the poppy plant, *Papaver somniferum,* which is indigenous to Asia Minor. The opium poppy is cultivated in other countries including Egypt, India, China and Persia. The milky juice is dried in the air and forms a brownish gummy mass. This is further dried and powdered to make the official powdered opium.

The pharmacologically active constituents of opium are alkaloids. These number well over a score but only three—morphine, codeine, and papaverine—have wide clinical use. In addition to alkaloids, opium contains a large number of chemical substances which do not contribute to the pharmacodynamic properties of the drug. These are organic acids, resins, gums, oils, sugars and protein-like bodies, and comprise about 75 per cent by weight of opium.

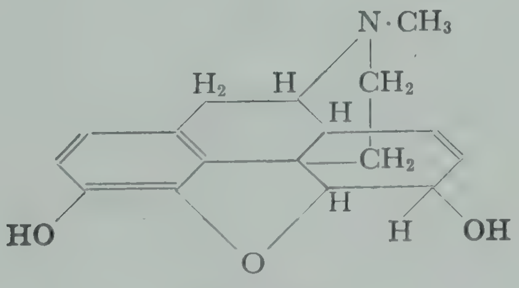
The alkaloids form about 25 per cent by weight of the opium. They may be divided into two distinct chemical classes—the *phenanthrene* and the *benzylisoquinoline* derivatives. These groups contrast sharply in their pharmacological properties. The main alkaloids of medical interest which occur naturally in opium and their approximate percentages are shown in Table 7. The many other natural alkaloids of opium occur in such small amounts and contribute so little to its actions that they are omitted from discussion. They are not readily available and have no clinical uses.

TABLE 7

THE ALKALOIDS OF OPIUM

GROUP	NATURAL ALKALOID	PERCENTAGE IN OPIUM
1. *Phenanthrene*	Morphine	10.0 (3 to 23)
	Codeine	0.5 (0.2 to 0.8)
	Thebaine	0.2 (0.2 to 1.0)
2. *Benzylisoquinoline*	Papaverine	1.0 (0.5 to 1.0)
	Narcotine	6.0 (0.75 to 10.0)
	Narceine	0.3 (0.1 to 0.5)

Chemistry of the Opium Alkaloids. Morphine is by far the most important phenanthrene alkaloid of opium and gives to the latter its predominant pharmacological characteristics. The exact structural formula of morphine has been the subject of considerable chemical research (*see* Small, 1932). The formula most commonly accepted today is that of Gulland and Robinson (1925) which is the following:



Morphine

This formula, while not yet entirely proved, accounts for more of the complicated facts of morphine chemistry than does any other. The morphine molecule can be seen to consist of a partially hydrogenated phenanthrene nucleus, an oxide bridge, a nitrogen containing chain, ethenamine $(—CH_2CH_2N(CH_3)—)$, attached in a very unusual way to the phenanthrene nucleus and constituting a part of a six-membered heterocyclic ring, and two hydroxy groups.

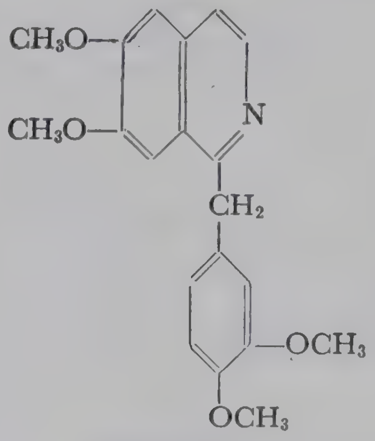
In the formula, the two hydroxy groups which are of basic importance for the actions of morphine are shown in bold-faced type. They are known as the *phenolic* and *alcoholic* hydroxy groups. Morphine has not been synthesized in the laboratory but many of its derivatives are made by the introduction of relatively simple chemical radicals into the hydroxy groups of the morphine molecule. Many of the naturally occurring phenanthrene alkaloids differ from morphine only by virtue of substituted radicals in one or both of these OH groups.

For example, *codeine* is methylmorphine, the methyl substitution being on the phenolic OH. If both hydroxy groups of morphine have methyl radicals inserted, dimethylmorphine or *thebaine* is formed. *Dionine,* a synthetic alkaloid, is produced by replacing the phenolic OH with an ethoxy group to form ethylmorphine. Diacetylmorphine or *heroine* (heroin) is another synthetic morphine derivative made by the acetylation of both OH groups. Dihydromorphinone, known as *dilaudid,* is formed by replacing the alcoholic OH with a ketonic oxygen and by hydrogenation to remove the adjacent double bonds. If the empirical formula of morphine is written as $HO \cdot C_{17}H_{17}ON \cdot OH$ with the phenolic OH on the left and the alcoholic OH on the right, the structures of the more important natural and synthetic phenanthrene alkaloids of opium can be represented in a simple manner as follows:

Natural alkaloids	*Synthetic alkaloids*
Morphine $HO \cdot C_{17}H_{17}ON \cdot OH$	Heroine $CH_3CO \cdot O \cdot C_{17}H_{17}ON \cdot O \cdot OCCH_3$
Codeine $CH_3O \cdot C_{17}H_{17}ON \cdot OH$	Dionine $CH_3CH_2O \cdot C_{17}H_{17}ON \cdot OH$
Thebaine $CH_3O \cdot C_{17}H_{17}ON \cdot OCH_3$	Dilaudid $HO \cdot C_{17}H_{19}ON{:}O$

Apomorphine is yet another synthetic alkaloid obtained by vigorous treatment of morphine with strong mineral acids to cause fundamental changes in the molecule. The oxygen bridge and the internal linkage of the N-containing chain are removed to give the structural formula presented on page 813.

Papaverine, the main alkaloid of the benzylisoquinoline group, is chemically and pharmacologically distinct from morphine and its related derivatives. The structural formula of papaverine is as follows:



Papaverine

Relationship between Chemical Constitution and Pharmacological Action. The phenanthrene alkaloids act chiefly on the central nervous system where a combination of depressant and stimulant effects is produced. The only other important action is on smooth muscle which is stimulated to contract. The benzylisoquinoline alkaloids are in sharp contrast by having only insignificant effects on the nervous system and a definitely antispasmodic action on smooth muscle. When opium is given, the actions of the phenanthrene alkaloids and especially those of morphine predominate.

As a result of careful study of the actions of morphine and its derivatives, definite pharmacodynamic properties have come to be assigned to each of its two hydroxy groups. The masking of the phenolic OH in morphine, as occurs in codeine, decreases the analgesic, respiratory, depressant and intestinal spasmodic actions, but the stimulant effects on the central nervous system are enhanced. Therefore compounds such as codeine and thebaine are much less narcotic than morphine and in large doses may produce convulsions, especially in certain species of animals which are susceptible to stimulatory effects of morphine and its derivatives. Indeed, thebaine can produce strychnine-like convulsions and should be classed with the central stimulants. On the other hand, when the alcoholic OH is masked, as by the introduction of an acetyl group to form heroine or by replacement with a ketonic oxygen to form dihydromorphinone (dilaudid), the narcotic and respiratory depressant properties of morphine are exaggerated. This is especially true if the alcoholic hydroxy group is entirely eliminated, as in the desoxymorphine compounds. When either the phenolic or alcoholic OH's are masked, the convulsant effects, as a rule, are increased and the emetic action is decreased.

From these basic facts, it would appear that the free phenolic OH in morphine is the basis for the analgesia, hypnosis, respiratory depression and constipation, and that the free alcoholic OH tends to counteract these effects. The integrity of both hydroxy groups is essential for a relative absence of excitatory phenomena. Thus codeine is more convulsant than morphine; heroine, though more narcotic than morphine, also produces greater stimulation of the nervous system. The emetic properties of morphine likewise appear to be connected with the free OH's and if either one of the hydroxy groups is masked, vomiting is less pronounced.

TABLE 8

EFFECTIVE DOSES IN MILLIGRAMS PER KILOGRAM OF ALKALOIDAL BASE

	CODEINE	MORPHINE	DILAUDID
Average Fatal Dose (mice)	241 *	531	84
Convulsions (mice)	161	531	67
General Depression (rats)	36.1	6.75	0.88
Analgesia (cats)	8.04	0.75	0.17
Respiratory Depression (rabbits)	1.3	0.15	0.011
Emetic Action (cats)	16.0 **	0.22	0.08
Exciting effect (cats)	8.04	0.57	0.17

* The lower toxicity of morphine as compared with codeine holds only for animals which are quite susceptible to the convulsant effects of these derivatives. Thus codeine is more toxic for mice although morphine is more lethal for man.

** Vomiting did not occur with any dose used; nausea (licking, with or without salivation) seen at dose indicated.

Compiled from data presented by Small, Eddy, Mosettig and Himmelsbach (1938).

In Table 8, compiled from the data presented by Small, Eddy, Mosettig, Himmelsbach and associates (1938), the differences between morphine (two free OH's), codeine (masked phenolic OH) and dihydromorphinone [dilaudid] (change in the configuration of the alcoholic OH) are clearly seen.

Other fundamental features of the morphine molecule have also been investigated. This work has largely been the result of an extensive cooperative research program, initiated in 1928 and still in progress, undertaken jointly by a number of chemists and pharmacologists under the auspices of the National Research Council, the Universities of Virginia and Michigan, the Rockefeller Foundation and the Narcotic Bureau of the United States Public Health Service. The object is ultimately to find potent analgesic substitutes for morphine which do not cause addiction and lack certain other undesirable properties. Scores of compounds have been investigated and the relation between chemical structure and certain definite pharmacological actions has been elucidated. The properties particularly studied are analgesia, depression, emesis, intestinal stimulation, respiratory depression, excitatory phenomena, and potentiality for causing addiction.

Not only have synthetic morphine derivatives, numbering over 125 compounds, been investigated, but also compounds simpler than morphine, yet resembling it in respect to certain features, have been studied. Thus, for example, it has been found that when the ethenamine ring is opened a considerable loss of typical morphine effects results. If phenanthrene itself is injected into animals, only mild sedation occurs; but, when a phenolic OH is added in the position occupied by the phenolic OH in morphine, the hypnosis is more marked and some evidence of obtundation of pain appears. When another OH is added in the position occupied by the alcoholic OH of morphine, narcotic effects are enhanced. Numerous radicals, including an N-containing open chain similar to ethenamine, have been attached to the phenanthrene nucleus in various positions and in each instance it has been found that the position occupied by the phenolic OH in morphine is the crucial one for the elicitation of depressant and analgesic effects. Because no proof exists that phenanthrene contributes an essential part to the action of morphine, other substances synthesized from the phenanthrene, phenanthrylene oxide, phenanthridine, dibenzofuran and carbazole series have been investigated. Many of the conclusions drawn from a study of the behavior of related drugs in the morphine series would seem to be applicable to similarly related derivatives of the dibenzofuran and phenanthrene series.

Of more than academic interest is the fact that compounds which may prove clinically useful as substitutes for morphine and codeine are beginning to emerge from the extensive plan of investigation outlined. Certain coal tar derivatives have already been synthesized which in animals, at least, compare favorably with codeine as analgesics and possess no euphoric quality. To mention but one of the more promising chemicals which may be valuable as a substitute for morphine, *methyldihydromorphinone* ("metopon"), in particular, deserves brief description. It has already received considerable pharmacological and clinical study but no conclusion is as yet justified concerning development of tolerance to it or its addicting potency in comparison with morphine. Relief of pain occurs quickly after the subcutaneous injection of two to seven mgm of the drug, and analgesia lasts for more than two hours (page 196). Most important is the fact that no respiratory depression or other serious untoward result has been noted. The phenomena disclosed by substituting methyldihydromorphinone for morphine in addicts and then withdrawing the substituted drug are clearly depicted in Table 11. Further clinical work is required before it can be determined whether habituation and dependence develop after continued medication with this chemical (Himmelsbach, Eddy and associates, 1938; Himmelsbach, 1939; Eddy, 1939).

For the details of this important field of investigation the interested reader is referred especially to the papers of Eddy and collaborators (1932, *et seq.*), and to the monograph by Small, Eddy, Mosettig and Himmelsbach (1938) which also contains an extensive bibliography.

Pharmacological Actions of Morphine

When opium is administered to man, the most prominent clinical effects are discernible on the central nervous system and the bowel. Morphine is responsible for the major actions of opium and therefore its pharmacological properties will be discussed in detail. The significant variations of other alkaloids of opium from the morphine pattern of action will be presented as occasion arises.

Central Nervous System. Morphine exerts a *narcotic action* in man manifested by analgesia and sleep. A significant feature of the analgesia is that it occurs before and often without sleep. When moderate amounts of morphine are given (up to 15 mgm), human subjects soon experience an euphoric, exhilarating drowsiness characterized by freedom from anxiety, muscular relaxation, rapid flow of uncontrolled thought and imagination, shortening of the time sense, disappearance of fears, doubts and inhibitions, and increased ease of discriminating and making decisions. There is inability to concentrate, difficulty in mentation, apathy, lessened physical activity, dimness of vision, and lethargy. Pain is relieved, hunger is abolished, and vomiting (when it occurs due to morphine) is not associated with the usual unpleasant emotional reactions, even when it is violent and repeated. The respiration is depressed and the pupils are somewhat constricted. If the external situation does not prevent it, sleep soon ensues and dreams may be prominent. The psychological effects enumerated outlast the analgesic action by many hours (Wolff and coworkers, 1940). Codeine produces psychological effects similar to morphine but milder in intensity.

When full therapeutic doses of morphine are given (15 to 20 mgm), the stage of euphoria, lessened activity and mental sluggishness quickly passes into one of deep dreamless sleep from which the patient is aroused with difficulty. Severe pain is relieved as a rule; the respirations are definitely slowed; the pupils are quite constricted; and recovery is characterized by after-depression, constipation and sometimes by nausea and vomiting. As the dose of morphine is increased beyond the ordinary therapeutic amounts, all the effects mentioned become more marked. Poisoning is characterized particularly by deep coma, markedly depressed respirations and pin-point pupils. With lethal doses of morphine, death occurs from respiratory failure.

The typical course of morphine action as presented is not always evident. Many factors may modify the effects of the drug, particularly idiosyncrasy and the level of reflex excitability of the nervous system. These will be discussed later but certain features of *morphine excitation* of the nervous system are mentioned at this point. Some individuals, especially women, are excited by morphine. This effect usually does not extend beyond nausea and vomiting due to a medullary stimulation which precedes depression; but, in rare cases, delirium and even convulsions may occur. Certain morphine derivatives and natural alkaloids of opium are more likely to produce these excitatory phenomena. Thus codeine does not produce progressive depression as its dose is increased but causes marked excitement. It has already been stated that thebaine resembles strychnine more than it does morphine and can elicit convulsions. Heroine is known to cause central excitation and is taken by the heroine addict for euphoric stimulation long after tolerance to the depressant effects has occurred. Apomorphine is the most potent direct stimulant of the emetic center. The chemical basis of the excitatory properties of morphine has already been discussed.

Certain species present clearly the excitatory effects of morphine for in some animals this alkaloid causes almost pure stimulation, convulsions and death by exhaustion. In the cat, for example, morphine causes wild mania and tonic and clonic spasms which last many hours and often end fatally. Even decorticated cats respond in this manner (Hambourger, 1937) and the stimulation therefore cannot be due to a release mechanism such as operates in the excitement stage of general anesthesia. Other species, including pigs, goats, asses and horses are stimulated by morphine. The alkaloid has thus been used to stimulate horses prior to racing. The dog is depressed by morphine but initially shows restlessness, nausea, vomiting and defecation, due to preliminary central excitation.

The *central depression* produced by morphine is considerably different from that caused by the hydrocarbon inhalation anesthetics. Morphine, even in small doses, causes a selective depression of the respiratory center whereas many anesthetics are respiratory stimulants. The general anesthetics also depress the motor cortex but this is evident only after large doses of morphine. An individual may be aroused from morphine narcosis and be in full control of his motor functions. Furthermore, analgesia occurs with the anesthetic drugs only when consciousness has been clouded or lost but morphine relieves pain before and often without producing unconsciousness. Morphine differs from the sedatives such as the barbiturates in its specific analgesic power, its respiratory depressant action and its relatively poor anticonvulsant potency.

Spinal Cord. The excitatory effects of morphine are particularly evident on the medullary vomiting center and the spinal cord. In spinal animals, the alkaloid can cause strychnine-like tetanus. The ability to produce stimulation of the cord is the chief reason why morphine is not useful as a sedative agent in strychnine poisoning and other convulsive syndromes. As the cerebrospinal axis is ascended, stimulation becomes progressively less marked. These facts allow the anatomical summary that "morphine depresses from above downward and stimulates from below upward." It is thus clear that morphine produces a peculiar mixture of excitation and depression of the central nervous system.

Peripheral Nerves. The peripheral nerves and sense organs are unaffected by morphine. The former practice of applying opium plasters and ointments locally to relieve pain was based on the belief that opium acted directly on nerve endings to cause analgesia. Pain is abolished only by the central actions of morphine and the local use of opium preparations is therefore irrational and obsolete.

Respiration. Morphine is a primary and continuous depressant of respiration by virtue of a direct action on the respiratory center. The effect is discernible with small doses insufficient to produce sleep or disturb consciousness. The action is a highly selective one and the degree of depression is directly proportional to the dose. Initially, as the rate decreases, the depth of breathing may increase sufficiently to raise the respiratory minute volume. Soon, however, the depth of respiration also diminishes and the respiratory minute volume falls. After toxic amounts of morphine, the number of respirations per minute may fall to three or four and respiratory arrest is the cause of death in acute morphine poisoning. The respiratory center depressed by morphine fails to react normally to stimuli. Whereas both the rate and depth of breathing are normally increased by carbon dioxide inhalation, after morphine the depth is affected much more markedly than the rate. After small doses of morphine which cause slowing of respiration and a reduced tidal volume, the vagal reflexes affecting respiration are exaggerated, phenomena commonly seen in response to a lowered alveolar carbon dioxide concentration (V. E. Henderson and Rice, 1939). Inasmuch as the alveolar carbon dioxide concentration is elevated in morphine depression, it is likely that the cells of the respiratory center are much less sensitive to carbon dioxide (Y. Henderson, 1938). Although Henderson and Rice noted in their animal experiments that small doses of morphine caused peripheral sensory stimuli to increase respiratory rate and ventilation, toxic doses in man tend to diminish or prevent the usual acceleration of breathing caused by painful stimuli. Cheyne-Stokes respiration is sometimes seen in severe morphine poisoning (Figure 16).

In addition to depressing respiration, morphine in small doses dulls the cough reflex and in large doses abolishes it. Dyspnea is also relieved by morphine through a depression of central sensory perception. This alkaloid is indispensable in the treatment of certain forms of cardiac dyspnea, especially the type known as "cardiac asthma" caused by pulmonary edema secondary to left ventricular failure.

Codeine is less depressant to the respiration than is morphine. Furthermore, as the dose of codeine is increased, commensurate slowing of the respiratory rate does not occur. In fact, large doses of codeine tend to stimulate the brain stem. Codeine is especially useful for its action in depressing the cough reflex. Doses of codeine effective in this regard are not as constipating as morphine and lack the serious addicting property of the requisite doses of the latter drug. *Heroine* is considerably more depressant to the respiratory center than is morphine, and at one time it was rather widely employed for depression of the cough reflex. However, the danger of addiction to heroine and the tendency of even small doses (two mgm) to abolish rather than dull the cough reflex contraindicate the use of this alkaloid in respiratory disorders. Heroine has no advantages over morphine or codeine. The action of *dionine* on respiration resembles that of codeine very closely. The effect of *papaverine* on respiration is typical of the benzylisoquinoline alkaloids which cause a mild stimulation of breathing through a direct stimulation of the respiratory center. The stimulation of respiration by papaverine, however, has no therapeutic usefulness. *Opium,* because of its papaverine content, is less depressant to respiration than its morphine content would indicate.

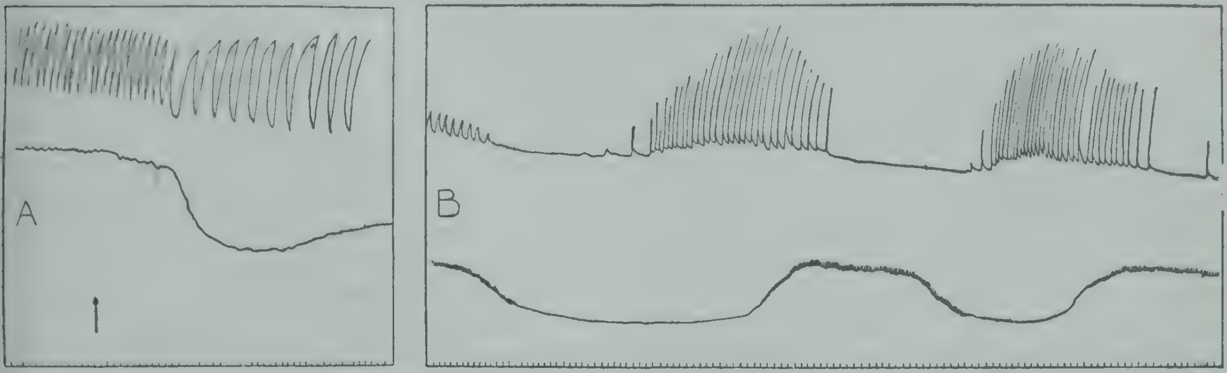


FIGURE 16. *The effect of morphine sulfate on respiration in the etherized vagotomized cat.*

Arrow indicates the intravenous injection of 10 mgm per kilogram of the alkaloid. Base line, time in five second intervals; lower tracing, blood pressure; upper tracing, respiration recorded with Cushny oncometer. *A.* The immediate effect consists in a slowing of the respiratory rate with an increase in depth. Note the fall in blood pressure following the intravenous administration of the drug. *B.* Twenty minutes later, and after total dose of 25 mgm per kg, medullary depression has led to Cheyne-Stokes respiration. Note how the periods of apnea and hyperpnea are reflected in the condition of the circulation. (After Barbour, 1914. Courtesy of the *Journal of Pharmacology and Experimental Therapeutics.*)

Pain. The relief of pain by morphine is the outstanding property of the drug and the one which clinically is most often sought. Morphine produces analgesia by a highly selective action and pain is relieved without obtundation of other modalities of sensation. The locus of this effect is entirely central and is thought to be in the optic thalami. Continuous dull pain is relieved more effectively than sharp intermittent pain. With sufficient amounts of morphine, however, it is possible to abolish nearly all forms of pain and thus morphine is the agent of choice for the severe pain of renal and biliary colic. The lightning pain of tabes dorsalis is one of the few types which resist morphine analgesia. In sharp contrast to the salicylates and related analgesics, morphine is effective against pain arising from viscera as well as from integumental structures, muscles and joints.

In a critical experimental analysis of the effects of opium alkaloids on the pain experience in man, Wolff, Hardy and Goodell (1940) have concluded that there are three components to the relief of pain afforded by opiates. First, morphine is capable of raising the threshold for pain perception. This factor operates chiefly when morphine is given *before* the painful stimulus is experienced, as when morphine is administered prior to surgical operation. When morphine is given for severe pain, the relief afforded is not due, in any large part, to the ability of morphine to elevate the pain threshold. Secondly, opiates alter the pattern of reaction to pain. This factor operates especially when the alkaloids are given for the relief of severe pain. The pain is still perceived but it no longer brings forth the usual responses (anxiety, fear, panic, withdrawal and flight). The patient is capable of tolerating the experience of pain when it is freed of its implications. This action of morphine is usually obtained within one-half hour after the drug is taken—at least one hour before the peak of the pain threshold-raising action is reached. Thirdly, opiates may induce sleep, and the investigators mentioned have determined that sleep in itself raises the threshold for pain by approximately 50 per cent.

Wolff and his associates also emphasize that there is a mutual antagonism between pain and the analgesic action of morphine and its congeners. For example, when severe pain is experienced for some time before morphine is administered, the subsequent ability of the drug to exert an analgesic action (*i.e.,* to raise the pain threshold) is limited or abolished. On the other hand, if the painful stimulus is introduced after the analgesic action of morphine has reached its peak (approximately 90 minutes after intramuscular injection), the perception of pain is less acute. These workers also observed that epinephrine, administered prior to morphine, decreased or abolished the pain threshold-raising action of the opiate. This is probably accountable for on the basis of the central excitatory effects of epinephrine (page 409), the experimental subjects having felt tense and excited long after the circulatory effects wore off. The significance of this finding arises from the fact that epinephrine is released from the adrenal medulla during pain.

Pupils. Morphine causes constriction of the pupils. The exact mechanism of the miosis is unknown. That it is central and not peripheral is indicated by the fact that local application of morphine to the eye does not affect the size of the pupil. Atropine counteracts the morphine-induced pupillary constriction. In morphine poisoning, the miosis is marked and pin-point pupils are pathognomonic. Marked dilatation occurs terminally as asphyxia intervenes. Tolerance does not develop to the miotic action of morphine. Thus the morphine addict continues to show constricted pupils.

The action of morphine on the pupil has been ascribed to a direct effect of the alkaloid on the pupilloconstrictor center (Edinger-Westphal nucleus). It may, however, result from paralysis of sympathetic pupillodilator centers in the hypothalamus. Evidence that the miosis may be due to depression of supranuclear inhibition of pupilloconstrictor tone is suggested by the fact that decortication in dogs prevents the pupillary effect of morphine. Those species which are excited by morphine usually show marked mydriasis. This is especially true in the cat. Even chronic decortication in this animal fails to prevent the pupillary dilatation following morphine.

Comparison of Opium Alkaloids in Respect to Clinical Features of Central Nervous System Depression. The members of the morphine group of alkaloids differ considerably in their degree and duration of analgesic action, the subjective depression and euphoria which they produce, and in the incidence of side-effects. All these properties are of importance to the physician in his selection of opiates. The data obtained from laboratory experiments (von Frey technic) on normal men by Seevers and Pfeiffer (1936) are particularly valuable in this respect, and the essential findings are summarized in Table 9.

That the variations in time required for peak analgesia are due to differences in the rate of absorption of the alkaloids after subcutaneous injection is indicated by the fact that after intravenous administration of the same doses peak analgesia occurred in 20 minutes with the four drugs. The investigators also found that neither the duration nor degree of analgesic action was as great after intravenous as after hypodermic medication, except for heroine which was more potent intravenously. Dilaudid, in particular, suffered a peculiar loss of efficacy after intravenous injection. Heroine was the most potent in respect to euphoria. This property was less prominent after intravenous injection, which is in contrast with the experience of the addict. The side-effects noted included nausea, vomiting, constipation, diarrhea and urticaria.

Table 9

CLINICAL COMPARISON OF CENTRAL DEPRESSANT EFFECTS OF OPIUM ALKALOIDS

Opium Alkaloid	Equivalent Analgesic Subcutaneous Doses	Time Necessary for Peak Analgesia After:		Descending Order of Potency * After Subcut. Admin. Regarding:			Untoward Side-Effects *
		Subcut. Admin.	Intrav. Admin.	Duration of Analgesic Action	Duration and Intensity of Subjective Depression	Euphoria	
	mgm	minutes	minutes				
Morphine Sulfate	10	60–90	20	1	1	2	1
Heroine Hydrochloride	1.0–2.0	30	20	4	3	1	4
Dilaudid Hydrochloride	0.8–1.0	90	20	2	2	3	2
Codeine Phosphate	64	30–60	20	3	4	4	3

Compiled from the data of Seevers and Pfeiffer (1936).
* Order of Potency: 1 =most; 4 =least.

Inasmuch as equivalent analgesic doses of the alkaloids caused varying degrees of subjective depression, it is clear that the mechanism of relief of pain is different from that of stupefaction. This conclusion is supported by the fact that maximal subjective depression occurred within five minutes after intravenous medication whereas the analgesic peak came 15 minutes later. Furthermore, after subcutaneous injection, analgesia often wore off before stupefaction became prominent. This differentiation between the mechanisms of analgesia and subjective depression is clearly seen in the barbiturates which are excellent somnifacients and poor analgesics. Scopolamine also elicits marked depression without analgesia. Conversely, the salicylates produce analgesia without stupefaction. The importance of this point rests in the fact that it is thus hopeful to search for morphine substitutes which will produce a maximum of analgesia and a minimum of subjective depression. Patients then need not be put to sleep in order to obtain relief from pain. Likewise, an investigation of 65 morphine derivatives with respect to their toxicity (mice), and their potencies as respiratory depressants (rabbits) and analgesics (cats) shows that these properties are dissociated (Sumwalt, 1938). This strengthens the conviction that synthetic morphine derivatives will be found which are satisfactory analgesics but do not cause respiratory depression.

The data of Seevers and Pfeiffer (summarized in Table 9) have been confirmed and extended, in all important respects, by the experiments of Wolff and coworkers (1940), some of whose conclusions have already been presented. These investigators devised a technic for measuring the pain threshold in man by means of a heat lamp focused on the skin of the forehead (Hardy, Wolff and Goodell, 1940). The peak analgesic action of doses of *morphine sulfate* (0.5 to 15 mgm) administered intramuscularly was reached in 90 minutes. The maximal analgesic effect of morphine proved to be a straight line function of the dose in the range between 0.5 and 15 mgm, but the increment of increase in pain threshold-raising action became progressively less as the 15 mgm amount was exceeded. Thus, the pain threshold was elevated 10 per cent by 0.5 mgm, 32 per cent by 5.0 mgm, 47 per cent by 8.0 mgm, 71 per cent by 15 mgm, but only 93 per cent by 30 mgm. The duration of the action on the pain threshold was three hours for 0.5 mgm, four hours for 2.0 mgm, over six hours for 8.0 mgm, slightly under seven hours for 15 mgm, and slightly over seven hours for 30 mgm.

With respect to *codeine,* the above investigators found that regardless of the amount injected (intramuscularly), the maximum pain threshold-raising effect was reached in approximately 90 minutes. The duration of action persisted approximately three hours with doses of 15 mgm, more than five hours with doses of 120 mgm. The threshold-raising action was proportional to the dose up to 60 mgm. Amounts larger than 60 mgm failed to cause any additional increase in pain threshold. For example, the threshold was elevated 20 per cent by 15 mgm of codeine, 30 per cent by 30 mgm, and 50 per cent by 60 mgm; but even 240 mgm failed to increase the threshold beyond 50 per cent. It is thus clear that there is little object in exceeding the dose level of 60 mgm. When codeine is compared with morphine, a 15 mgm dose of the former is equivalent to two mgm of the latter in being capable of increasing the pain threshold by 20 per cent; 60 mgm of codeine equals eight mgm of morphine in that each elevates the threshold by 50 per cent; but, as stated, additional amounts of codeine cause no further increase in threshold.

With regard to *dihydromorphinone hydrochloride* (dilaudid), it was established that a three mgm dose injected intramuscularly elevated the pain threshold 100 per cent (equivalent to 30 mgm of morphine). *Pantopium hydrochloride* (page 208) given parenterally in the dose of 20 mgm raised the pain threshold 35 per cent (equivalent to eight mgm of morphine, approximately). *Methyldihydromorphinone* ("metopon") injected in the dose of 6.6 mgm increased the pain threshold by 90 per cent (comparable to 30 mgm of morphine). The peak effect appeared in 90 minutes and remained for one and one-half hours, the control level again being reached after seven hours. Vomiting occurred and the pupils were constricted. The subjects were unable to differentiate the psychological and physiological effects of metopon (6.6 mgm) from those caused by morphine (30 mgm) or dilaudid (three mgm), but the sequelae were of shorter duration.

Smooth Muscles. The second important locus of action of the opium alkaloids is on certain smooth muscles. The phenanthrene derivatives contrast with the benzylisoquinoline drugs in that they cause contraction of smooth muscle whereas the papaverine group produces relaxation. Morphine, for example, tends to cause contraction of smooth muscles with the notable exception of those of the blood vessels. Papaverine, however, produces muscular relaxation, particularly in blood vessels.

Gastro-intestinal Tract. The *constipating effect* of opium was utilized by the the Ancients. The use of opium preparations by the Chinese for relief of diarrheas and dysenteries preceded by many centuries their employment for central depression. The typical action of opium on the bowel is due mainly to morphine. The antispasmodic action of the benzylisoquinoline alkaloids is quite weak. For clinical purposes, therefore, opium and morphine may be viewed as acting similarly on the enteric tract.

The experimental and clinical research on the complex actions of opium alkaloids on the bowel has been quite extensive. The results vary considerably and this may be attributed to differences in experimental technics. From the mass of available evidence, certain effects of morphine on the digestive apparatus appear definitely to be established. A most important conclusion is that these phenomena are due entirely to local actions of the alkaloid on the bowel and not to any effect on the central nervous system. The interested reader is referred for details to the review of this subject by Krueger (1937).

Stomach. Morphine causes an initial retardation of secretion of hydrochloric acid by the stomach. Gastric motility is also lessened and the tone of the antral portion of the stomach is increased. In addition, the pyloric sphincter is contracted. The result of these effects of morphine is to cause a slowing of the passage of gastric contents into the duodenum. This delay in the stomach may last for 12 hours or more, and contributes about one-half to the total gastro-intestinal delay which is the basis of morphine constipation. Resection of the extrinsic gastric nerves and the administration of atropine have little influence on these actions of morphine on the stomach; but in man, atropine can be shown to inhibit the increase in gastric tone caused by morphine (Veach, 1937) (Figure 17).

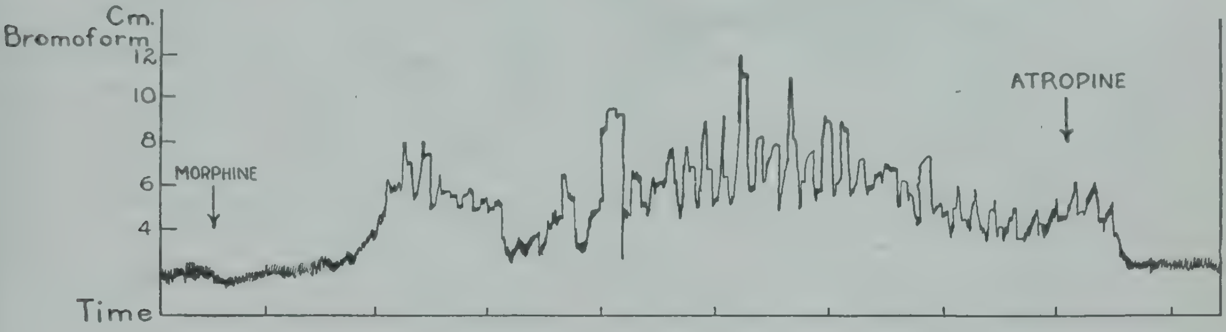

Figure 17. *The effect of morphine on the motility of the empty, intact, normal human stomach.*

Gastric motility recorded by means of a balloon connected to a bromoform manometer. Time, in units of 2.1 minutes. The intravenous injection of 7.5 mgm of morphine sulfate produced a gradual increase in tonus and in frequency of rhythmic contractions. The intravenous injection of 0.3 mgm of atropine sulfate completely abolished the rhythmic contractions and diminished the tonus. (After Veach, 1937. Courtesy of the *Journal of Pharmacology and Experimental Therapeutics.*)

Small Intestine. Both biliary and pancreatic secretions are diminished by morphine and digestion of food in the small intestine is delayed. Propulsive movements of the small bowel are interfered with by the alkaloid chiefly as a result of an increased muscular tone. Water is more completely absorbed from the chyme due to the delayed passage of the bowel contents. The viscosity of the chyme is thus greater than normal and further delay occurs. The tone of the ileocecal valve is also increased. Large doses of atropine may counteract in part the intestinal responses to morphine. These features of morphine action on the small intestine combine to cause about one-third to one-fourth of the total constipating effect of the alkaloid.

Large Intestine. Peristaltic waves in the colon disappear after morphine and the tone of the musculature of the large bowel is increased to the point of spasm. The resulting delay in the passage of the contents causes considerable desiccation of the feces which in turn prevents their advance along the colon. The tone of the anal sphincter is greatly augmented and this, combined with inattention to the normal sensory stimuli for the defecation reflex, contributes to morphine constipation. Unawareness of the necessity to defecate is due to the action of morphine on the perceptual functions of the cortex and is the only factor contributed by the central effects of the drug. The relative importance of this factor cannot easily be determined. At times, especially with the use of larger doses of opiates, it must be considerable. Omitting this factor, however, the other features of morphine action on the large intestine combine to contribute about one-quarter of the entire constipating effect.

Codeine is definitely less constipating than morphine. *Heroine* when given in equi-analgesic amounts has very little gastro-intestinal effect but in larger stupefacient doses, it does produce constipation. *Dilaudid* also appears to be less constipating than morphine. *Papaverine* and the benzylisoquinoline alkaloids tend to relax the intestinal musculature (Figure 18). This action is relatively weak, however, and when opium is administered the papaverine content is insufficient to offset the constipating effects of morphine. The addict does not develop tolerance to the actions of morphine on the bowel and he continues to suffer from alternating constipation and diarrhea.

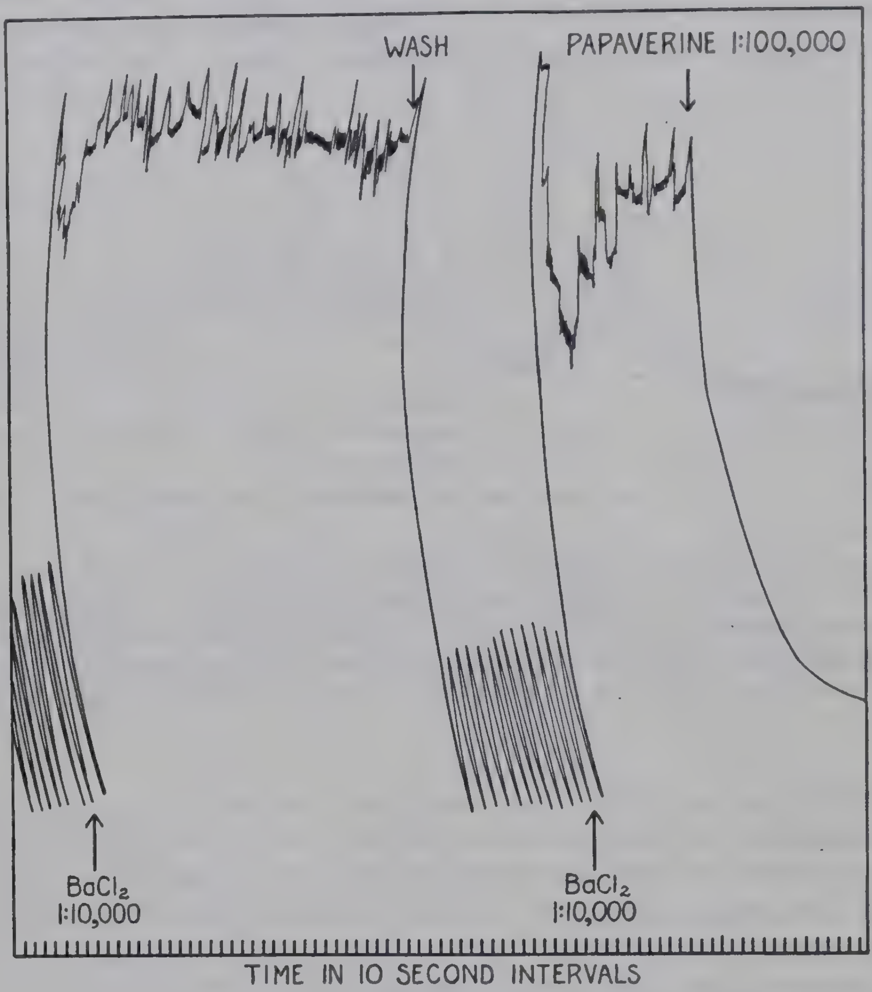

Figure 18. *The antispasmodic action of papaverine on the small intestine.*

Isolated strip of rabbit jejunum. Spasm produced by barium chloride (1:10,000) persists until the drug is washed from the organ bath. Papaverine hydrochloride (1:100,000) is capable of promptly counteracting the spasm produced by barium, and in addition normal peristalsis is temporarily suspended.

The nauseant and emetic actions of morphine and its derivatives have already been discussed. These responses are purely central in origin and result from a direct stimulation of the medullary emetic center.

Whereas the gastro-intestinal responses to opium and morphine are correctly viewed as unpleasant side-effects when these drugs are given for narcosis, yet these same actions at times become desirable therapeutic objectives in themselves. This is especially true in patients with gastro-intestinal hemorrhage, exhausting diarrhea or dysentery, peritonitis, etc.

Biliary Tract. Experiments performed on patients with T tubes in the common bile duct for drainage after exploratory operations show definitely that the hypodermic injection of 10 mgm of morphine sulfate causes a marked increase in biliary pressure (Walters and coworkers, 1937). The pressure rises from the normal of zero to 20 mm of water to a level of from 200 to 300 mm. This effect begins within five minutes after injection, reaches its peak in 15 minutes and persists for two hours or more. Symptoms often accompany the increased pressure and vary from epigastric distress to typical biliary colic. It is quite clear, therefore, that the relief afforded by morphine in biliary spasm is purely cerebral in origin. *Codeine* (60 mgm), pantopon (20 mgm) and *dilaudid* (two mgm) all cause a similar increase in intrabiliary pressure but the rise is neither as rapid nor as high as that after morphine.

Biliary spasm produced by morphine is evident roentgenographically as well as manometrically and a sharp constriction becomes apparent at the lower end of the common bile duct. This prevents emptying and thus causes the intraductal pressure to rise. Atropine (0.9 mgm subcutaneously) does not relax the morphine-induced spasm. Papaverine (32 mgm intravenously; 180 mgm intramuscularly) has no effect on the elevated biliary pressure caused by morphine. Inhalation of amyl nitrite is the most valuable agent for relaxing this type of biliary spasm (Figure 58). Nitroglycerin (0.6 mgm) administered sublingually also decreases the elevated intrabiliary spasm (Figure 59). The effect is less marked but more prolonged than that produced by amyl nitrite. Theophylline with ethylenediamine (0.24 gram) given intravenously is also quite effective (Figure 59). In Figure 19 is shown a record of the effects of morphine sulfate on biliary pressure.

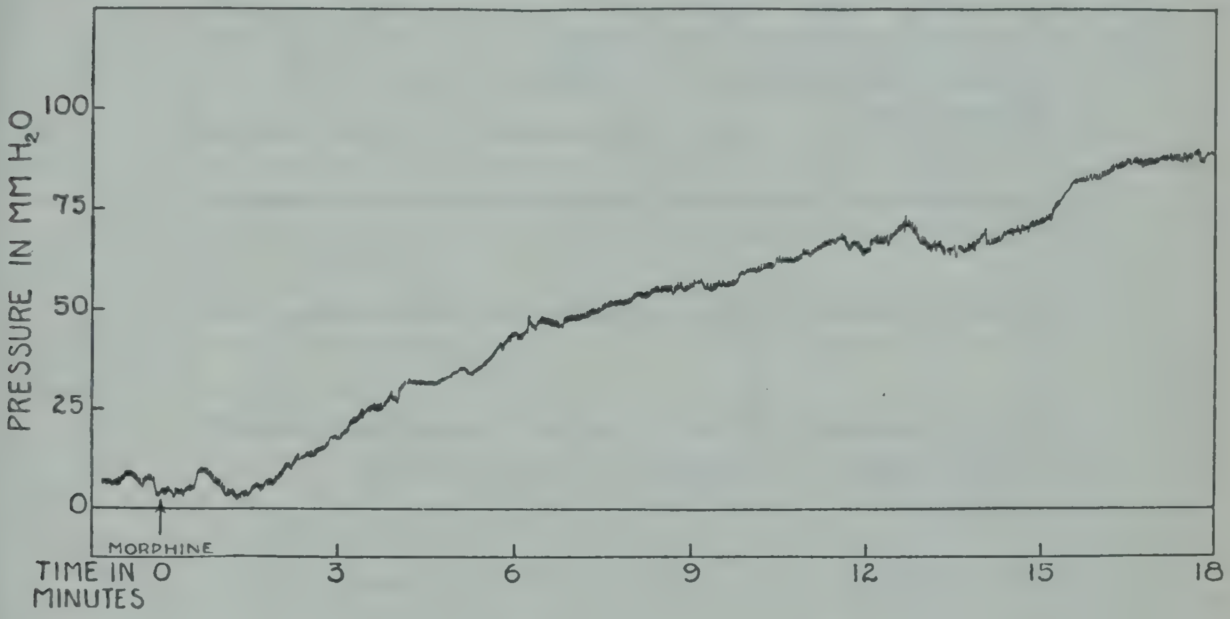

Figure 19. *The effect in man of the subcutaneous injection of 10 mgm of morphine sulfate on intrabiliary pressure.*

Kymographic tracing obtained by means of a water manometer connected to a T-tube inserted into the common bile duct for prolonged biliary drainage. Note the gradual rise in pressure which at times may reach a level of 300 mm of water. Dilaudid causes a similar rise. Typical biliary colic may occur. (After Butsch, McGowan and Walters, 1936. Courtesy of *Surgery, Gynecology and Obstetrics.*)

Ureter and Urinary Bladder. The intact human ureter responds to morphine by an increase in tone and amplitude of contraction. In more than a score of normal persons in whom ureteral activity was followed by hydrophorographic tracings and radioscopy, hypodermic injection of eight to 30 mgm of morphine caused the ureteral responses to appear within five minutes and to persist for at least three hours (Figure 20) (Ockerblad and collaborators, 1935). These clinical results confirm the experimental data obtained on animals. Papaverine and benzylisoquinoline drugs depress ureteral activity with respect to tone and rate and amplitude of contractions.

Atropine, although it has little effect on the ureter when given alone, can eliminate the morphine-induced ureteral spasm when given subcutaneously in a dose of 0.6 mgm. This is in sharp contrast to the inefficacy of atropine in relieving the gastro-intestinal and biliary spasm caused by morphine. The relief of renal colic by morphine is clearly due to central analgesia because the local action on the ureter would tend to aggravate the pain. These results also suggest that atropine should accompany morphine medication for ureteral colic, and that a mixture of opium alkaloids containing papaverine might offer greater relief than does morphine alone.

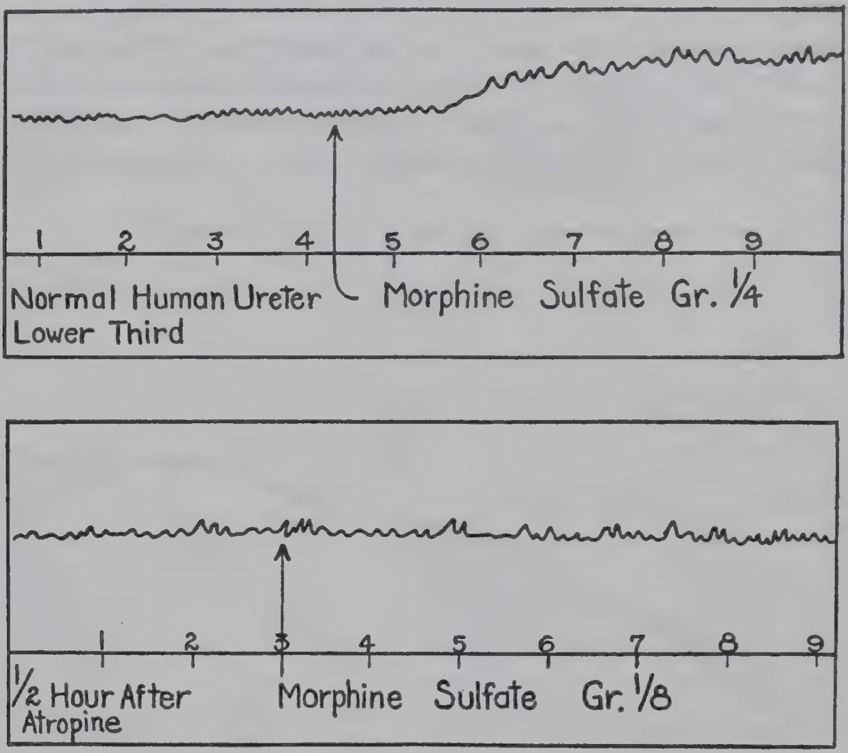

Figure 20. *The effects of morphine sulfate on the normal human ureter.*

Kymographic tracings obtained by means of a ureteral catheter and water tambour; time in minutes. The upper tracing shows the increase in ureteral tone and amplitude of contraction produced within two to three minutes by 15 mgm of morphine sulfate given subcutaneously. The responses may last longer than three hours. The lower tracing shows that the administration of 0.6 mgm of atropine sulfate prevents the ureteral response to morphine. (After Ockerblad, Carlson and Simon, 1935. Courtesy of the *Journal of Urology*.)

The tone of the detrusor muscle of the *urinary bladder* is augmented by morphine which therefore causes urinary urgency. The tone of the vesical sphincter is also enhanced by morphine which may thus make urination difficult. Furthermore, the patient is often inattentive to the stimuli arising from the bladder as a result of central depression, and catheterization therefore may be necessary. This is especially true in morphine poisoning.

Other Smooth Muscles. The *bronchial musculature* is stimulated to contract by morphine, but this effect is rarely if ever apparent from the use of therapeutic doses in man. Papaverine relaxes the bronchi. The *uterine muscle* is not directly affected by doses of morphine used in obstetrical analgesia. The alkaloid can influence the progress of labor in other ways, however, especially by preventing cooperation of the mother and depressing fetal respiration.

Cardiovascular System. Therapeutic amounts of morphine or its allied alkaloids have little if any effect on the blood pressure, heart rate or rhythm. Changes which occur are usually secondary to lessened physical activity or sleep. The vasomotor and vagal centers in man are unaffected by doses of morphine that readily cause respiratory depression. It requires toxic amounts of the alkaloid to produce central vasomotor depression, and the blood pressure falls only relatively late in the course of morphine intoxication. Even this fall is largely the result of asphyxia. This is evident from the fact that artificial respiration or administration of oxygen will cause the blood pressure to rise despite the persisting medullary depression. Anoxia results in capillary paralysis and if it is unrelieved shock follows. For this reason, the respiration and not the circulation receives most attention in cases of morphine poisoning.

Higher concentrations of morphine than can be attained clinically are required to affect the myocardium directly. The T waves in the electrocardiogram may occasionally be altered or inverted after large doses of morphine. The phenomenon may be due to respiratory depression causing relative anoxia of the myocardium. Errors may arise in the interpretation of the electrocardiogram of a patient suspected of acute coronary thrombosis if large amounts of morphine were recently administered to control pain.

Papaverine tends to relax the coronary vessels and in this manner may improve the circulation to the heart muscle. The actions of papaverine on blood vessels are discussed on page 208.

Skin. After therapeutic amounts of morphine in man, cutaneous blood vessels are relaxed. As a result, the skin of the blush area (face, neck, upper thorax) becomes flushed and hot. The mechanism of this vascular action is unknown but it appears to be a direct one on the blood vessels.

Sweating. Sweating is common after the administration of the opium alkaloids, especially morphine. Its cause is not apparent but may be related to an increased cutaneous blood flow. When Dover's powder is given as a diaphoretic, sweating is due in part to the opium content but more perhaps to the nausea caused by the ipecac.

Pruritus. Pruritus is not unusual after administration of the morphine alkaloids, and it is thought to be due to changes in cutaneous circulation. Both itching and sneezing are more apparent as the action of the opiate wears off. The nasal itching after morphine is the basis for the lay conception than an addict continuously scratches his nose. Allergic reactions are not uncommon and urticaria may be prominent. Marked anaphylactoid phenomena may result, especially from codeine administered intravenously.

Metabolic Effects. Morphine may cause a fall in *body temperature.* This occurs especially with large doses and is the result of lessened muscular activity, increased heat dissipation due to peripheral vasodilatation, and lessened sensitivity of the central mechanism for temperature regulation. With therapeutic doses of morphine, the depression of body temperature is not significant. The *metabolic rate* in man may be lowered slightly within the first hour after hypodermic injection of 10 to 20 mgm of morphine. This effect is secondary to a decrease in muscular tone as a result of central depression. The *hyperglycemia* noted after morphine in animals is inconstant, and the effect of the alkaloid on blood sugar in man is clinically unimportant. The rise in blood sugar is in some way related to the release of sympathin for only by complete sympathectomy can one completely abolish the hyperglycemia (Bodo and associates, 1938). The metabolic changes from overdoses of morphine such as marked hyperglycemia, glycosuria, increase in blood lactic acid, decrease in carbon dioxide combining power of the blood, etc., are caused by the anoxia resulting from the depression of respiration.

Local Actions. It has been stated that the opium alkaloids have no local anesthetic action and that their local use for analgesia is thus irrational. Indeed, the phenanthrene alkaloids are quite irritant to the mucosa and abraded skin. This is particularly true of *dionine*. The reactive mucosal hyperemia which this chemical produces when applied locally is employed in the treatment of indolent corneal ulcers, uveal exudates and vitreous opacities. A few drops of a solution of dionine hydrochloride (two to 10 per cent) are instilled into the conjunctival sac to cause vascular dilatation and therapeutic hyperemia. The drug may also be incorporated in an ophthalmic ointment (10 per cent) or a little of the dry powder itself may be placed in the eye.

Absorption, Fate and Excretion of the Opium Alkaloids. *Absorption.* The opium alkaloids are readily absorbed from the gastro-intestinal tract. The intact skin is not permeable to morphine but the scarified epithelium allows some of the drug to enter the circulation. The differences in time necessary for the hypodermically injected morphine alkaloids to manifest their actions are due to variations in rates of absorption from the subcutaneous tissues. When the drugs are given intravenously, they all act after the same interval of time.

Fate. Morphine is partly excreted from the body but mainly destroyed in the tissues. In man, 90 per cent is detoxified, especially by the liver. Temporary storage of morphine prior to destruction occurs mainly in the liver and skeletal muscles. Detoxification proceeds slowly. Only one-half of the total amount is destroyed in the first 24 hours. Inasmuch as the narcotic effects of a single dose are usually over within four hours, it is clear that some change must occur in the morphine prior to its destruction in the body.

Excretion. Excretion is almost entirely by way of the urine. In man, about one-tenth of the ingested drug is excreted in the urine and this occurs within the first four hours. A small fraction is eliminated in the feces even when morphine is given parenterally. The inconsequential amount excreted in the gastric juice does not warrant the dangerous procedure of continuous gastric lavage in morphine poisoning. Small amounts of morphine may be excreted in the milk when large doses are taken. This may at times be of importance because suckling infants are quite sensitive to the drug and addiction of nurslings has been reported. Traces of the alkaloid may appear in the saliva, sweat and other secretions. Morphine readily crosses the placental barrier and enters the tissues of the fetus. Indeed, the newborn child may show withdrawal symptoms if *in utero* it has been repeatedly exposed to morphine.

Codeine, in contrast to morphine, is largely excreted in the urine. About 80 per cent of the codeine administered can be accounted for in this way. Papaverine is not recoverable in the urine, feces or tissues, and its fate in the body is unknown. It is probably destroyed.

Tolerance. A characteristic feature of the phenanthrene alkaloids of opium is the tolerance to them which develops as a result of their repeated use. Tolerance does not occur uniformly to all the manifestations of morphine action. The depressant effects on the nervous system, such as respiratory depression, analgesia and stupefaction, fail to appear after continued employment of the drug unless the dose is increased. Tolerance does not occur to the excitatory responses elicited by the opium alkaloids. Thus codeine or heroine addicts experience stimulation. Also the effects on the bowel and pupillo-constriction continue and the morphine habitué manifests miosis and suffers from constipation alternating with diarrhea.

Cross-tolerance exists between the various phenanthrene alkaloids, and the person tolerant to morphine is also tolerant to dilaudid, codeine and heroine. Experimentally it has been shown that there is also a cross-tolerance between the emetic effects of morphine and apomorphine.

Different individuals require varying periods of time before the repeated administration of morphine results in tolerance. As a rule, however, after about two weeks of continued use of the same dose of alkaloid the usual depressant effects fail to appear. This time interval, however, may vary widely in either direction. When medication ceases, tolerance usually disappears within a few days to two weeks, and small doses will again produce characteristic depression. If the use of the drug is resumed, however, tolerance develops more rapidly than it did initially.

Large doses may eventually be taken by the tolerant person. The addict, for example, may ultimately use daily 20 to 200 times the ordinary therapeutic dose of opiate. Tolerance is never absolute, however, and a dose exists which is capable of producing death from respiratory depression even in the addict. Overdosage of opiate through error or from the misjudging of the degree of tolerance is a common cause of fatality among addicts. On the other hand, the tolerant person can receive much larger doses than he is accustomed to without any evidence of untoward results. Thus, Light and Torrance (1929) injected 30 grains of morphine intravenously in an addict within two and one-half hours, and no change occurred in pulse, respiration, blood pressure or other vital signs. The usual dose for this individual was only four grains. Again, the tolerance of the addict for morphine can be increased within three to five days from one gram daily to four grams daily without causing any detectable physiological changes.

The *mechanism of tolerance* to morphine is unknown. Various theories have been proposed but none of these satisfies all features of the phenomenon or survives rigorous examination. There is no evidence that the tolerant person excretes the drug more readily. Decreased absorption cannot be the explanation because large doses are tolerated when given intravenously. It has been claimed that tolerance is due to an ability of the body to destroy morphine more rapidly than normal. Many experimental data oppose this view. As stated, addicts tolerant to large oral doses are also tolerant to the same dose given by vein, a route which allows the full concentration of morphine rapidly to reach the brain cells before the mechanism of detoxification can effectively begin to operate. Furthermore, it is difficult to explain the persistent sensitivity to small amounts of morphine of certain brain centers and the intestine of the tolerant person if the alkaloid is destroyed more rapidly. Interesting clinical data on the fate of morphine have been obtained by Light and coworkers (1929–1930). They found that, regardless of the dose administered, addicted individuals, in a manner similar to that of normal persons, always excrete about 10 per cent of the morphine within four hours. The remaining 90 per cent rapidly undergoes a chemical change in the tissues and is no longer recoverable as morphine. Evidence for this exists in the fact that, after abrupt withdrawal, only 10 per cent of the last dose taken can be recovered in the urine. Withdrawal symptoms and craving appear as soon as this fraction is excreted, that is, after four hours. Similar results have also been obtained by other workers in normal and addicted dogs, all of which excrete the same percentage of the amount administered regardless of the size of the dose. Thus the rates of destruction and elimination of morphine are more closely related to the dose taken than to the extent or duration of addiction.

There is some evidence that tolerant animals may store more morphine in skeletal muscles than do the non-tolerant, but this requires further confirmation. The postulate of an "antimorphine" immune substance in tolerant patients has received no experimental support. Indeed, the evidence is strongly against the existence of such a substance. The most acceptable theory is that tolerance to morphine is a cellular phenomenon, that is, certain cells of the brain acquire the ability to function normally despite the presence of concentrations of morphine which ordinarily would depress their activity. In this respect, cellular tolerance to morphine resembles that to alcohol.

Idiosyncrasy and Variations in Response. Idiosyncrasy to the opium alkaloids manifests itself in many ways. *Nausea and vomiting* after morphine are fairly frequent in some patients, especially women. The basis for this excitation has already been discussed. When morphine is indicated in a patient known to respond to it with vomiting, the emesis can often be circumvented by giving a small preliminary dose of the drug which barely stimulates the emetic center. This is followed in 15 to 30 minutes with the remaining larger fraction of the full therapeutic dose which begins to take effect at a time when the vomiting mechanism has passed its stimulatory phase and is depressed. Other excitatory phenomena occurring after the administration of opium alkaloids are *tremors,* rarely *delirium,* more rarely convulsions, and sometimes *insomnia* as a late sequel. Hypersensitivity to pain after analgesia has worn off is nearly always noted. This hyperalgesia occurs after the administration of other drugs which relieve pain and can hardly be classed as an idiosyncrasy.

Allergic phenomena are not unknown after the administration of morphine and its derivatives. Urticaria and skin rashes occur, and contact dermatitis has been reported in nurses and pharmaceutical workers (Jordan and Osborne, 1939). Pruritus and sneezing have already been mentioned. Codeine is apt to cause wheals at the sight of injection, and marked anaphylactoid reactions have been reported to occur after the intravenous use of this drug. In some patients, codeine causes rather severe epigastric pain.

Infants are especially susceptible to the central depressant actions of morphine. The sensitivity is particularly noted before weaning, during which time great care must always be observed in using any preparation containing morphine. One drop of laudanum is reported to have caused alarming symtoms. Children, in contrast, are more tolerant of morphine (per pound of body weight) than are adults. *Old and debilitated patients* are more sensitive to the depressant actions of morphine and the dose should therefore be reduced.

The patient's illness and the state of the reflex excitability of the nervous system also condition the response to morphine. Thus individuals with *cerebral edema, cardiac psychoses* or *fever* may be excited by the drug. Persons with *myxedema* often react with marked narcosis to small doses of morphine, and this alkaloid must be prescribed with caution when the metabolic rate is low. Hyperthyroid patients, in contrast, usually tolerate morphine very well. Individuals suffering from *severe pain* can withstand large amounts of morphine without manifesting subjective or respiratory depression. For example, the person with pain from acute coronary thrombosis may receive with safety three or even four times the usual therapeutic dose of morphine before relief is obtained. There appears to be little basis for the belief that morphine is contraindicated in chronic nephritis, and the alkaloid may afford considerable symptomatic benefit in uremia.

Patients with *pruritus* may suffer an exacerabation of itching due to the administration of opiates. When *increased intracranial pressure* exists, care is required in the use of morphine due to the increased likelihood of depression of respiration. Morphine also tends to elevate the intracranial pressure (Kennedy and Wortis, 1931). In a person with an *hypertrophied prostate* or *ureteral stricture,* the use of morphine may precipitate acute urinary retention requiring repeated catheterization. The use of morphine in *bronchial asthma* is often dangerous and has caused death.

Preparations, Doses and Routes of Administration of Opium and Its Alkaloids. *Powdered Opium,* U.S.P., B.P. (Meconium, Thebaicum). The source, chemistry and alkaloidal composition of opium have already been given. Powdered opium is a brown, bitter, granular powder supplied for clinical use in capsule, tablet or pill form. The average adult dose is 0.06 gram taken orally. This is equivalent to six mgm of morphine because the official morphine content of opium is 10 per cent by weight. Formerly opium had a peculiar and characteristic odor detectable in the excretions of the patient, but the official tincture is now deodorized.

Opium is also available in the form of *Gum Opium* (U.S.P.) and *Granulated Opium* (U.S.P.) The dose of either is the same as for the powder. The N.F. contains an *Extract of Opium,* one gram of which represents two grams of opium and the dose of which is 0.03 gram. The B.P. contains an identical preparation, *Dry Extract of Opium. Aromatic Powder of Chalk with Opium,* B.P., contains 2.5 per cent of powdered opium. The dose is 0.6 to 4.0 grams (equivalent to 1.5 to 10 mgm of morphine). The above preparations are infrequently employed.

Tincture of Opium, U.S.P., B.P. (Laudanum; Tincture of Deodorized Opium). This tincture is a hydro-alcoholic solution containing 10 per cent of opium (one per cent of morphine). The average adult dose is 0.3 to 2.0 cc, taken orally.

Camphorated Tincture of Opium, U.S.P., B.P. (Paregoric). This tincture contains 0.4 per cent of opium (B.P., 0.5 per cent), or 0.04 per cent morphine. Also included are benzoic acid, camphor and oil of anise. The average adult dose is four cc which corresponds to 16 mgm of opium or 1.6 mgm of morphine. Paregoric by tradition is used especially for children, but represents a needlessly complex therapeutic survival of a former day.

Powder of Ipecac and Opium, U.S.P., B.P. (Dover's Powder). This contains 10 per cent each of ipecac and opium, and consists of a white or very light brown powder. The average adult dose is 0.3 to 0.6 gram, the equivalent of three to six mgm of morphine, respectively. The powder has been employed especially as a diaphoretic, and the mechanism involved has been discussed. The drug is no longer extensively used.

Ipecac and opium are also available together in *Tincture of Ipecac and Opium* (Tincture of Dover's Powder), N.F., dose 0.5 cc, and *Syrup of Ipecac and Opium* (Syrup of Dover's Powder), N.F., dose 4.0 cc.

Compound Mixture of Opium and Glycyrrhiza, U.S.P. This drug, known as "Brown Mixture," is another therapeutic relic. It contains 12 per cent of paregoric, some tartar emetic and a little sweet spirit of niter. It is needlessly complex and little used today. The average adult dose is four cc, taken orally.

Morphine. The alkaloids of opium, especially morphine and codeine, are employed much more extensively than the galenical preparations. Morphine is available as the alkaloidal base, but is usually prescribed in the form of its water-soluble salts. The two most common preparations are *Morphine Sulfate,* U.S.P. and *Morphine Hydrochloride,* N.F., B.P. The B.P. also includes *Morphine Tartrate.* These salts are bitter white powders, quite soluble in water and possess characteristic alkaloidal incompatibilities. Solutions of morphine salts are not irritating on injection.

Salts of morphine are also available in two official solutions. *Solution of Morphine Hydrochloride,* B.P., is an unflavored hydro-alcoholic solution containing one per cent of the alkaloidal salt. The dose is 0.3 to 2.0 cc (three to 20 mgm of morphine). *Compound Syrup of White Pine with Morphine,* N.F., contains only 0.04 per cent of morphine sulfate in compound syrup of white pine. The dose is four cc (1.6 mgm of morphine) or more.

The average oral adult dose of a morphine salt is eight to 20 mgm, but the amount varies with the patient's illness, factors of idiosyncrasy and the level of reflex excitability of the nervous system. The hypodermic dose is somewhat smaller. Occasionally a salt of morphine (2.5 to 15 mgm) may be given intravenously, as in emergencies when analgesia is needed quickly or when the regular preoperative dose of opiate has been forgotten or cannot be given soon enough (Betlach, 1937). The analgesic effects start immediately and reach their peak in 20 minutes.

The dose of opiates for children is best learned as such and modified to suit the particular case. In general, however, for infants over 10 months of age, the dose may be calculated on the basis of weight in pounds ($\frac{\text{wt}}{150} \times$ adult dose). For infants under 10 months of age, this dose should be halved ($\frac{\text{wt}}{300} \times$ adult dose).

Codeine, U.S.P., B.P. Codeine is available as the free alkaloidal base and in the form of its water-soluble salts. The most common salts of codeine are *Codeine Sulfate,* U.S.P., and *Codeine Phosphate,* U.S.P., B.P. The latter has the advantage of being much more soluble in water (1:2.3 as compared to 1:30). The average dose for adults is 16 to 60 mgm, given orally or hypodermically. Smaller amounts may be used when repeated medication is required.

Codeine is methylmorphine and the chemical basis for its pharmacodynamic differences from morphine has been presented. Codeine may be viewed as a weakened morphine which fails to cause proportionately greater narcotic effects as the dose is increased. Indeed, large amounts of codeine cause excitement, not depression. The analgesic potency of codeine is less than one-sixth that of morphine. If 60 mgm of codeine fail to relieve pain, larger doses rarely succeed (page 196) and are likely to cause restlessness and excitement. Codeine is only one-fourth as potent as morphine in its ability to cause subjective and respiratory depression. For example, the sleep induced by codeine is not as sound or refreshing as that from morphine, and serious respiratory depression is practically unknown even from large therapeutic amounts of the alkaloid. Death directly ascribable to codeine is practically unknown and the lethal dose for man cannot be stated. Nausea, vomiting, constipation and miosis are all less prominent after a given amount of codeine than after one-quarter this amount of morphine. Codeine is excreted to the extent of 80 per cent in the urine and is thus handled by the body in a manner considerably different from that for morphine.

Both tolerance and addiction occur to codeine. Withdrawal symptoms may not necessarily be less severe than in morphine withdrawal (Table 11; page 217). Codeine is rarely used by drug habitués, unless as an adulterant, because it does not produce the desirable degree of euphoria in the potential addict. The large doses required make trafficking in it difficult. When codeine is substituted in morphine addicts, five times as much may be needed to replace morphine and prevent symptoms of withdrawal. It must be reemphasized that codeine is an addictive drug, and the opinion current in some quarters that the alkaloid is benign in this respect is entirely without foundation (Himmelsbach, 1934).

Heroine (Heroin). Heroine is no longer an official drug in the U.S.P., but is included in the B.P. (*Diamorphine Hydrochloride*). Its importation and manufacture in the United States are prohibited by law, although the present available supply may be legally dispensed. The usual salt prescribed is the hydrochloride. The chemistry of heroine has already been presented. The dose of heroine is one-fourth that of morphine, that is, two to five mgm. Heroine is one of the most analgesic of the morphine derivatives, being from four to eight times as potent as morphine in this respect. It is also four or more times as depressant to the respiration. When given hypodermically, its analgesic action comes on more quickly than is the case with the other opiates. Heroine is excreted unchanged almost entirely by the kidney. It is said that in the addict the alkaloid is no longer recoverable in the urine. This requires confirmation.

The danger of heroine lies in the ease with which addiction to it occurs, due to the intense euphoria which often supplants subjective depression, and the absence of unpleasant side-actions such as vomiting and constipation. The type of addiction which heroine produces is of a serious nature. The heroine addict is difficult to treat, usually relapses after apparent cure and often represents a dangerous, asocial and criminal type of personality. He not only experiences euphoria but this is intermingled with excitation. Whereas the morphine addict takes his daily requirement of morphine in order to keep normal and prevent the appearance of withdrawal symptoms, the heroine habitué continues his drug rather for the euphoric excitation it affords. Considering its dangers, heroine has no indispensable advantages over morphine.

Dilaudid, N.N.R. This derivative of morphine, first described in 1923, is *dihydromorphinone hydrochloride.* It is a fine, white, odorless, crystalline, water-soluble salt, the chemistry of which has been given. The average adult dose of dilaudid is one-fourth or less than that of morphine, namely, two to four mgm. This may be given orally, hypodermically or by suppository. The duration of analgesic action of dilaudid is definitely shorter than that of morphine. Slower absorption and hence longer action can be obtained by the use of rectal suppositories. If given at bedtime, a night's relief from pain may often be obtained in this manner.

Dilaudid is about ten times more analgesic than morphine but only about four times more somnifacient. This allows dilaudid to be used for relief of pain with a minimal hypnotic effect, and sleep need not occur in order to obtain analgesia. The margin of safety of dilaudid is no greater than that of morphine. Side-actions from dilaudid, such as nausea, vomiting, and constipation, are apparently less marked than from morphine. Euphoria is also less evident after dilaudid than after morphine.

Both addiction and tolerance occur to dilaudid. Although some (but not all) animal experiments indicate that the drug is somewhat less likely to cause addiction than is morphine, clinical evidence on this point does not support such a conclusion. Cases of addiction to dilaudid have been reported; thus it is essential to use the alkaloid with the same precautions which are employed for morphine. In fact, the shorter analgesic action of dilaudid and the consequent necessity to step up the injection rhythm when the drug is used for the relief of chronic continuous pain favor the more rapid development of dependence on dilaudid as compared with morphine (King and associates, 1935; Daland, 1936). The phenomena seen after substituting dilaudid for morphine in addicts and then withdrawing the substituted drug are clearly depicted in Table 11. The Federal Narcotic Regulations naturally apply to the use and sale of dilaudid.

Dionine. Dionine is available as *Ethylmorphine Hydrochloride,* U.S.P. It is a synthetic derivative consisting of a white or faintly yellow, odorless powder which is quite soluble in water. Dionine may be viewed for therapeutic purposes as having the same pharmacological properties as codeine. Dionine, by tradition perhaps, is rarely employed for its systemic effects but is used only in the eye for the local irritation it produces.

Thebaine. This natural alkaloid of opium is not used clinically. It is a convulsant poison which produces strychnine-like stimulation rather than narcosis.

Pantopon. Pantopon, also called *omnopon* and *pantopium hydrochloride,* is a mixture of the purified opium alkaloids in the proportions occurring naturally. Thus it is a purified opium and is devoid of inert material. Pantopon has four times the morphine content of opium and by weight is close to 50 per cent morphine. The usual therapeutic dose is 20 mgm. It is available for oral use and for parenteral injection. Pantopon has the obvious advantage that it can be injected whereas opium preparations cannot.

The claims made for pantopon, that it produces fewer side-actions and allows the benefits of the central action of morphine and the peripheral antispasmodic effect of papaverine, are not substantiated. The papaverine content of pantopon is so small that it cannot contribute much to the total response. Clinical evidence indicates that the analgesic potency of pantopon is not materially greater than would be expected on the basis of its morphine content (Hayman and Fox, 1937; Wolff and coworkers, 1940).

Papaverine Hydrochloride, N.F. Papaverine is the most important member of the benzylisoquinoline group of opium alkaloids. It is marketed as the water-soluble (1:40) hydrochloride salt which consists of a white, crystalline, odorless and slightly bitter powder. The average adult dose is 30 to 80 mgm orally or intramuscularly, and 10 to 60 mgm intravenously. The toxicity of papaverine is very low and the ingestion of more than ten times the therapeutic dose has not resulted in untoward effects. Because it is contained in opium, papaverine comes under the Federal Narcotic Regulations despite the fact that it is devoid of narcotic action.

The pharmacological properties of papaverine have already been contrasted with those of morphine and may be summarized here. The actions of papaverine on the central nervous system are negligible and the drug causes neither sleep nor analgesia in therapeutic doses. Large amounts may actually increase reflex excitability. Papaverine relaxes many smooth muscles of the body, especially those of blood vessels. This relaxation occurs particularly if spasm exists. In those smooth muscles exhibiting phasic activity, tone is decreased and the amplitude and frequency of contraction are lessened. The drug does not paralyze the muscle cell which still responds to drugs and stimuli causing contraction. The muscles responding to the alkaloid are those of the bronchi, gastro-intestinal tract, ureters, biliary system and blood vessels, including the coronary arteries. Essex and associates (1940), for example, studied the effect of papaverine on the coronary circulation in trained unanesthetized dogs by means of thermostromuhr units placed on the coronary arteries. They found that the drug markedly enhanced coronary blood flow when given intravenously in doses comparable to those employed clinically, a finding in agreement with the observations of Anrep on the human heart-lung preparation.

The antispasmodic action of papaverine, however, is not clinically useful in all instances. Papaverine is not nearly as effective as epinephrine in bronchial asthma. Its value in the therapy of angina pectoris is also equivocal. Papaverine does not appear to relax the spasm induced by morphine in the human biliary ducts. Thus, the drug lacks the general usefulness of the nitrites as an antispasmodic.

The best therapeutic results have been obtained with papaverine in patients with peripheral or pulmonary arterial embolism. Papaverine given intravenously has prevented amputation of limbs and preserved life. The drug acts not on the obstructed vessel but by increasing collateral circulation in reflexly constricted vascular beds. Symptoms such as pain, paresthesia and paresis may be completely relieved and adequate circulation restored within a few minutes after the intravenous injection of 20 to 100 mgm of papaverine hydrochloride. The drug is a useful medical adjunct to embolectomy or therapy by passive vascular exercise. The peripheral vasodilatation produced by papaverine has also proved of value in cases of threatened gangrene, as from ergotamine, and it may be of service in certain other forms of peripheral vascular disease.

In *Raynaud's disease,* Mulinos and associates (1939) have obtained promising results from the use of papaverine hydrochloride (60 to 120 mgm) administered intravenously in conjunction with histamine iontophoresis. Littauer and Wright (1939) report that papaverine hydrochloride (30 mgm) given intravenously was uncertain in action and generally ineffective in producing vasodilatation in patients with *thromboangiitis obliterans* or *arteriosclerosis obliterans.*

In *pulmonary embolism,* papaverine may be injected intravenously in the dose of 30 mgm or more. One mgm of atropine may be administered simultaneously by the same route. In a review of a number of cases of pulmonary embolism treated with papaverine, Takats and Jesser (1940) point out that 18 of 22 patients survived (82 per cent) as compared with a control group of 100 cases in which there were only 13 survivals (13 per cent). These figures, although not conclusive, are quite impressive.

Narcotine. This chemical is another opium alkaloid of the benzylisoquinoline group. Despite its name, narcotine is not narcotic and, in general, resembles papaverine in its pharmacological actions. Narcotine has no therapeutic uses.

Narceine. This alkaloid occurs in opium and belongs to the papaverine group. It lacks specific pharmacological properties, probably because of its insolubility and the consequent lack of absorption. It has no clinical uses.

Acute Morphine Poisoning

Acute morphine poisoning usually results from attempts at self-destruction or from clinical overdosage. It is difficult to state the exact dose of morphine which is toxic. The susceptibility to morphine of infants, the aged and myxedematous individuals has been mentioned. Others are quite tolerant to large doses, especially those suffering severe pain. The addict, of course, can withstand much larger doses than he usually takes. As a rule, however, the toxic dose of the alkaloid for a normal adult who is not in pain is about 60 mgm. Serious symptoms nearly always follow the ingestion of 100 mgm of the drug, and the outlook becomes progressively less hopeful as amounts greater than this are taken. Doses of 250 mgm usually cause death.

In fatal cases, death occurs in about six to 12 hours after the drug is taken, although it may result within the first hour. The longer the patient survives the better are his chances for recovery, because destruction and excretion of the poison are taking place and effective therapeutic measures may be instituted. The postmortem findings are purely those of asphyxia. Morphine can be recovered from the urine, tissues and excreta and can be identified pharmacologically and chemically. These are important considerations for medico-legal cases.

Symptoms. By the time he is seen by the doctor, the patient who has ingested an overdose of morphine is usually asleep or stuporous. If a large dose has been taken, ordinarily he cannot be aroused and soon sinks into a *profound coma.* The breathing is quite slow and only two to four respirations may occur per minute. Cheyne-Stokes breathing may be noted. The patient is *cyanotic* and the skin of the face shows a mottled purple flush. The *blood pressure* at first is maintained near normal because morphine has little direct effect on the vascomotor center or the cardiovascular system. As the respiratory exchange becomes poorer, however, the blood pressure falls progressively until it reaches shock levels. If adequate oxygenation is restored early, the blood pressure will again rise; but if anoxia persists untreated for any length of time, the capillaries are damaged and *shock* supervenes. More fundamental measures are then necessary to elevate the blood pressure. The cardiovascular abnormalities in morphine poisoning are thus almost entirely secondary to the respiratory depression which should therefore be the focal point of therapy.

The *pupils* are symmetrical and pinpoint in size in acute morphine intoxication. As asphyxia intervenes, they may dilate markedly. Overdoses of chloral hydrate and barbiturates can also cause miosis but it is not as constant or as pronounced as after morphine. *Urine formation* is considerably depressed and urine flow may cease secondary to the low blood pressure. The *body temperature* falls and the skin becomes cold and clammy. The *skeletal muscles* are flaccid, the jaw relaxed and the tongue may fall back to block the pharyngeal airway. The *Babinski great toe sign* is often positive and, if not, it may become so during periods of apnea. Occasionally *skin rashes* and urticaria develop, and if the stupor is not great reflex scratching of the skin and nose due to pruritus may be prominent. Atypical features of excitation may occur in morphine intoxication prior to the depression. These include restlessness, delirium and vomiting. When death occurs, it is due to *respiratory failure* and the heart beats feebly for a short interval after breathing ceases. Death may also be due to shock or *pulmonary complications,* especially pulmonary edema or pneumonia.

Diagnosis. The triad of coma, pinpoint pupils and greatly depressed respiration strongly suggests morphine poisoning. Other central depressants such as alcohol, chloral hydrate and barbiturates may simulate this intoxication. In few other conditions, however, are the respirations so characteristically depressed, the pupils quite so small, or the coma so rapid in onset and progressive in development as in morphine poisoning. The history is helpful, if obtainable, and at times chemical examination of the suspected material or of the urine and gastric contents may be necessary to establish the diagnosis beyond question.

Treatment. Therapy follows the same general plan as for barbiturate intoxication, but attention is focused especially on the respiration. Prompt diagnosis and effective therapy are needed to save life. If the patient can be kept alive for 12 hours or longer, the prognosis improves. However the danger of late pulmonary complications is ever present.

Lavage of the stomach should be instituted if the poison was taken orally, and this should be done even if the patient is not seen until late. Some morphine may still be in the stomach and the stimulation incident to the passage of the gastric tube is not undesirable. The lavage water should be either a 1:2000 solution of potassium permanganate or it should contain one cc of tincture of iodine. Emetics should not be used because they are rarely successful and may add to the morphine depression. The practice of continuous or repeated gastric lavage should be abandoned. Little if any morphine is excreted into the stomach and the patient may be seriously depleted of electrolytes by such therapy. Magnesium sulfate, 30 grams in solution, should be administered before the stomach tube is removed in order to expedite the passage of unabsorbed poison through the bowel.

Stimulation of the respiration is accomplished by the use of caffeine with sodium benzoate, 0.5 gram given parenterally, or by enemas of strong black coffee. Theophylline with ethylenediamine may also be used as a medullary respiratory stimulant and is given in doses of 0.5 gram intramuscularly or intravenously. The xanthines may be repeated at intervals as needed. Ephedrine sulfate, 20 to 40 mgm intramuscularly, is not only a medullary stimulant but also raises the blood pressure and acts centrally to lessen narcosis. It may be repeated hourly if necessary. Inhalation of carbon dioxide (10 per cent) in oxygen is a potent measure for stimulation of breathing. Coramine, metrazol and atropine may also be used. The latter should be given only once and in a dose not to exceed 1.5 mgm. Oxygen therapy may be continued for hours if necessary. Reflex respiratory stimulation such as that caused by inhalation of ammonia or injection of camphor is usually valueless in the severer grades of morphine poisoning. If breathing has almost ceased, artificial respiration should be resorted to without delay and continued until an adequate stream of oxygen can be fed by catheter directly into the trachea. If the heart is functioning and oxygen is being delivered to the lungs, the patient will not readily die. This simple fact is lost sight of too often in the emergency treatment of the patient *in extremis.*

The blood pressure, if low, can often be elevated merely by improving the oxygenation of the patient's blood; this is the reason that attention to the respiratory exchange is so important. Several of the drugs used to stimulate respiration, especially ephedrine, may also raise the blood pressure. If the blood pressure is low due to shock from protracted capillary anoxia, a shock regimen must be followed as outlined elsewhere.

The degree of narcosis should be lessened if possible. Ephedrine and caffeine assist in this objective. If stupor has not yet occurred, every attempt should be made to keep the patient awake and he should be kept moving if possible. Strychnine and picrotoxin are not employed because morphine itself is a stimulant of the spinal cord. Diuresis has not been proved of value in promoting recovery from morphine poisoning, but copious amounts of fluid may be given empirically to insure against dehydration and acidosis. Furthermore, the kidneys should be kept functioning because they represent the chief channel for excretion of that morphine which escapes destruction in the body. Hypertonic solution of glucose given intravenously is a good diuretic agent, and also provides readily utilizable food and assists in maintaining blood volume if shock is impending.

Additional measures consist of maintenance of body temperature, frequent changes in the patient's posture to forestall development of hypostatic pneumonia, and prevention of aspiration during gastric lavage. Prolonged coma requires that attention be given to the intake of food, fluids and electrolytes and to distention of the urinary bladder. A long period of sleep usually precedes full return to consciousness. After recovery, the severe obstipation can be treated by enemas and laxatives. The itching, headache, nausea, vomiting and confusion during the recovery period may require symptomatic therapy.

Acute poisoning by heroine or dilaudid is treated in the same manner as poisoning by morphine. Codeine rarely causes fatalities because overdoses may stimulate rather than depress, and the chances for recovery are better. Poisoning by papaverine has not been reported.

Opium Addiction: Chronic Morphinism

The narcotic alkaloids of opium head the list of drugs to which addiction occurs, and this fact is a major consideration in their therapeutic use. The opium habit has existed for centuries in the Orient where the drug is habitually smoked by millions of people. In the United States and Europe, the pure alkaloids are used, and the addiction takes a more serious form.

Etiology. The etiology of narcotic addiction varies but the habitué himself cannot be believed regarding the origin of his habit. It is likely that only a small percentage becomes addicted as a result of the therapeutic use of opiates. The vast majority of narcotic habitués are constitutional psychopathic inferiors, and the habit is only one manifestation of their fundamental personality defect. In this sense, they do not differ from chronic alcoholic addicts. The use of an opiate provides an escape mechanism from reality, a way of release from the failures and disappointments of everyday life, a means of bridging the gap between ambition and accomplishment. Some of these individuals start the habit as a result of evil associates, of curiosity or as a means of dissipation. When a "thrill" or "kick" is desired, according to the language of the addict, the dose must be increased as tolerance develops in order to duplicate the original dreamy state of euphoria. Most cocaine and heroine addicts are in this category. On the other hand, the few persons who acquire the habit accidentally from the therapeutic use of a narcotic increase their dose as little as possible and continue to take the drug only to prevent unpleasant withdrawal symptoms.

Incidence. The exact incidence of narcotic addiction in the United States has been a subject of considerable discussion and inquiry (*see* Terry and Pellens, 1928). Estimates as high as one million have been offered but this figure is considered much too large by many authorities. The number of addicts is probably not over 30,000 (about two in 10,000) at the present time (Report by the Government, 1939).

Types of Drug Used. The narcotics used in the United States are particularly heroine, morphine and cocaine,* in the order named. Heroine has greater powers of addiction than other drugs, produces greater euphoria and "stimulation," requires smaller doses and is easier to traffic in illicitly. The addiction it causes is dangerous and difficult to cure. Probably 75 per cent of addicts in the Eastern seaboard area use heroine. Codeine addiction is rare because the drug produces practically no euphoria and possesses relatively weak addicting power. The few codeine addicts that are found are usually patients who originally received the drug for clinical purposes.

Every conceivable method and route is used to get the narcotic into the body. Morphine and heroine, however, are ordinarily taken hypodermically and occasionally intravenously; cocaine and also heroine are employed by snuffing. The use of opium preparations is rare in the United States. Occasionally, however, a paregoric addict is discovered. The daily dose of this mixture may reach a quart a day.

Time Required for Addiction. Addiction occurs after varying periods of time. While it usually requires more than two weeks, it may occur in a few days and in some unstable personalities after only a few doses. Great care should therefore be exercised not to prescribe narcotics for a longer period of time than is absolutely necessary. The continuous employment of opiates to relieve the pain of terminal diseases or neoplastic growths does not come under the scope of the present discussion and addiction under such circumstances is unavoidable.

Amount of Drug Taken. The amount of drug taken by the addict may be remarkably large. De Quincey in his "Autobiography and Confessions of an Opium Eater" remarked that at one time he took 133 drams (over 500 cc) of tincture of opium daily. This is the equivalent of 4.7 grams of morphine, or 300 times the single therapeutic dose. One of Light's patients (1929) employed 4.5 grams of heroine daily by subcutaneous injection. The average daily allotment of heroine, cocaine or morphine more often ranges between 0.5 and 1.8 grams. The patient cannot be trusted to give an honest report on his dose because he feels that by exaggerating his needs he will more easily succeed in obtaining what he desires. In estimating the daily requirements of an addict it is necessary to establish the amount which keeps him comfortable and prevents withdrawal symptoms.

---

* The designation of cocaine as a narcotic is inconsistent with the definition given on page 27, and merely refers to the inclusion of cocaine under the Federal Narcotic Regulations.

Mechanism of Narcotic Addiction. The cause of addiction to certain drugs is unknown. Many theories have been advanced but none is entirely satisfactory (*see* review by Tatum and Seevers, 1931). Intimately connected with the cause of drug addiction is the problem of tolerance. Tolerance to opium alkaloids cannot be attributed to increased excretion, decreased absorption or accelerated destruction. Unexplained is the fact that the addict is tolerant to nine or more times the dose which he requires to prevent symptoms of abstinence, and that such a dose does not increase the interval before the drug is again requested. In addition to manifesting marked tolerance to morphine, the addict is psychically and physiologically dependent upon the chemical for his stability and well-being. The term *habituation* refers to the psychic and emotional dependence on the drug, whereas the term *dependence* signifies the more basic physiological need for the narcotic. When morphine is withdrawn, a characteristic abstinence syndrome appears which is a psychosomatic complex of signs and symptoms clearly showing both the psychical and organic dependence of the addict on the drug. The psychic component of addiction may be more prominent than the physical, and the intensity of habituation is thus not necessarily proportionate to the severity of dependence (Himmelsbach, Eddy and coworkers, 1938). Addiction is particularly likely to occur to those narcotics causing analgesia of short duration, which must therefore be given at frequent intervals, and which produce euphoria of long duration in relation to the period of relief from pain.

Also closely concerned with the mechanism of addiction are the nature and physiological basis of the withdrawal symptoms. If one could describe with certainty the pathological and functional changes which occur in the addict when his drug is withdrawn and correlate these adequately with the symptoms which occur, the alterations caused by morphine in the tissues of the addict would yield more readily to study. The exhaustive clinical investigation of Light and associates (1929) offers little promise in this regard. Their findings do not explain the train of symptoms which ensues when the opiate is withdrawn.

Light and his coworkers have therefore been forced to the conclusion that withdrawal symptoms may be largely hysterical. However, others disagree and believe that there is an organic basis for such symptoms. They point out that neurocytological changes in the brain of addicts have been described but these do not appear to be constant or specific. Disturbances in water metabolism and the autonomic nervous system have also been advanced as the basic alterations in addiction, but these would seem to be the consequence and not the cause of the phenomenon. Tatum, Seevers and Collins (1929), on the basis of experiments on monkeys, have proposed that withdrawal symptoms represent the unmasking of hyperexcitability produced by the continued use of morphine. This interesting suggestion needs corroboration.

The effects of chronic morphinism and morphine withdrawal in chimpanzees on various physiological and behavioral functions have been described in the monograph by Spragg (1940).

Symptoms and Effects of Morphine Addiction. The popular conception of the morphine addict as a cunning, cringing, malicious and degenerate criminal who is shabbily dressed, physically ill and devoid of the social amenities could not be farther from the truth. When the addict is properly dressed and fed and receives his daily drug requirement, he cannot be distinguished from other persons. He remains in excellent health and suffers no inconvenience or physical abnormalities unless he ceases to take the drug. The euphoria experienced at first soon disappears unless the dose is continuously elevated. Some addicts practice the habit for the euphoria they obtain, but an appreciable number do it only to escape from the distress which quickly follows withdrawal. Brilliant and famous persons have been narcotic addicts and their affliction often has remained unknown even to their closest associates. The only adequate test of morphine addiction is the occurrence of withdrawal symptoms upon cessation of the narcotic.

Excellent health and productive work are thus not incompatible with narcotic addiction. This holds true particularly for morphine because, as already stated, tolerance is not developed to the stimulant effect of heroine and cocaine, and addicts to these drugs are often dangerous characters. Extensive clinical and laboratory examinations of a large number of hospitalized persons addicted to morphine for from five to 20 years failed to reveal change in any tissue, fluid or function of the body which definitely differentiated the addict from the normal non-addicted individual (Light and collaborators, 1929). The only departures from normal were the tendency to a low red blood cell count, a high white blood cell count, a somewhat increased blood cholesterol and lactic acid, and a decreased phosphate level of the blood. Also there were noted a slight delay in gastric secretory response to a test meal, albuminuria in one of six addicts, and a lag in the return of the blood sugar to normal following oral ingestion of dextrose. In a well controlled study, Williams (1939) observed that morphine addiction in man is associated with hydration of the blood to a moderate degree.

Ill health, crime, degeneracy and a low standard of living are the result not of the pharmacological effects of morphine but of the sacrifice of money, social position, food and self-respect in order to buy the daily dose of drug. Inasmuch as narcotics are ordinarily obtained through illicit channels, the cost is high. It is difficult for a normal person to appreciate how completely the desire and necessity of maintaining an adequate supply of narcotic dominate the entire thought and action of the addict and become the major purpose of his existence.

Diagnosis. The facts cited leave little doubt that the addiction to morphine is often difficult to recognize. Some habitués experience severe constipation alternating with diarrhea. Many, but not all, show contracted pupils. There may be scars and abscesses of the skin due to repeated infections if the drug has been injected without aseptic technic. The distribution of these scars is over those skin areas to which the patient has ready access, that is, anteriorly; but this is true only if the drug is self-injected. The physician's suspicion should also be aroused if a patient fails to respond characteristically to a dose of morphine which is ordinarily sufficient to cause depression. In the last analysis, the only true diagnostic test for addiction is the occurrence of a fairly typical train of abstinence symptoms upon withdrawal of the drug.

Withdrawal Symptoms. The character and severity of the withdrawal symptoms depend on many factors. These include the type of treatment instituted, the dose of narcotic and interval used, the duration of addiction, and especially the health and personality of the patient. If it is absolutely clear to the addict that regardless of his complaints, pleas and demands he will not receive an opiate, the course of withdrawal is much easier. The purpose of the cure is often important in determining the cooperativeness and symptoms of the patient. For example, those forced against their will to undergo therapy are difficult to manage. On the other hand, many confirmed addicts "take the cure" in order to be able to start all over again with a dose which is small and therefore cheap, and which again produces the euphoria which tolerance prevents them from experiencing. Such patients will plead for a "pick-up" dose of one-quarter grain of morphine about the third or fourth day after withdrawal. If they experience euphoria from this small dose they know that their tolerance is broken and that their susceptibility to morphine is restored. They then continue with the remainder of the treatment quietly and cooperatively. Their object has been attained (Light and associates, 1929).

Although psychic factors are undoubtedly important in determining the character of withdrawal symptoms, some of the signs and symptoms are so constant and severe as to suggest a deeper basis than hysteria, despite the fact that such a basis remains undisclosed. Symptoms start within four to 12 hours or longer after the last dose of morphine is omitted, depending on the interval used by the addict. They are usually quite severe within 48 hours, reach their peak in 72 to 96 hours and are definitely on the decline by the fifth day. Symptoms of morphine abstinence have ceased within five days to two weeks, usually having disappeared by the eighth day. At the height of the effects of withdrawal, tolerance is still present as can be shown by the injection of the dose to which the patient was accustomed. Such an injection relieves all subjective distress and completely restores the equanimity of the patient within five to 30 minutes. After withdrawal symptoms have ceased, tolerance has disappeared and death may readily occur from taking the former large doses.

The first symptoms to be noted are lacrimation, yawning, sneezing, sweating, anorexia and tremor. These are followed by voluble expressions of desire for the drug, restlessness, psychic depression, irritability, muscular weakness, mydriasis, fever and increased respiratory rate. There then follow increasing irritability, insomnia, marked anorexia, yawning which becomes violent, severe sneezing, excessive lacrimation and coryza, and hoarseness. Weakness and depression are pronounced. Marked chilliness alternating with vasomotor disturbances of flushing and excessive sweating are characteristic and annoying. Vomiting may occur, and colic and diarrhea are usually prominent. The chilliness experienced by the addict has its physical counterpart in the skin which shows striking pilomotor activity and resembles the skin of a plucked turkey. This is the origin of the expression "cold turkey" to signify abrupt drug withdrawal without substitution therapy. Often at the end of the first eight hours or thereabouts the addict falls into a deep sleep, known as a "yen," which may last for from eight to 12 hours, but from which he awakens more restless and miserable than before.

The failure to take fluid and food, coupled with vomiting, sweating and diarrhea, results in weight loss, dehydration and acidosis. Muscle pains in the abdomen, back and extremities are also quite characteristic and are particularly severe in the popliteal region. There may be rigidity in the right lower quadrant and this, combined with abdominal pain and a commonly occurring leukocytosis, may simulate appendicitis. Severe muscle tremors and twitchings, headache, diplopia, delirium, occasionally mania, and seminal emissions or orgasms complete the picture. Sometimes cardiovascular collapse may appear and this may require the administration of morphine to prevent death. The cardinal features of the abstinence syndrome have been summarized in Table 10, from the publication of Himmelsbach, Eddy and associates (1938), which lists the signs in their approximate order of appearance but chiefly with regard to their significance for an estimation of the intensity of the withdrawal syndrome.

TABLE 10

THE ABSTINENCE SYNDROME

(Himmelsbach, Eddy and associates, 1938)

MILD (+)	MARKED (+++)
Yawning	Fever
Lacrimation	Increase in respiratory rate
Rhinorrhea	Restlessness
Perspiration	Insomnia
MODERATE (++)	SEVERE (++++)
Muscle tremor	Vomiting
Gooseflesh	Diarrhea
Loss of appetite	Weight loss
Dilated pupils	

As symptoms subside, the patient begins to eat, drink and sleep and rapidly regains his composure and weight. Physical and laboratory examinations during and after withdrawal reveal little information to which the dramatic symptoms can be ascribed. During withdrawal, there occur some weight loss, a polymorphonuclear leukocytosis, a slight rise in blood cholesterol, often some measure of anhydremia, and a reduction in performance of physical fitness tests. When morphine is readministered or when well-being has returned after completion of treatment, re-examination of the patient shows little change in these findings which therefore offer a meager basis on which to explain the symptoms. Following readministration of morphine, however, there does occur uniformly a rise in the percentage oxygen saturation of the venous blood, the significance of which is not immediately apparent (Light and collaborators, 1929).

Those who have had most experience with addicts during the abstention period cannot decide whether the symptoms are psychic or organic in origin. The diplopia, muscle twitchings and leukocytosis, for example, certainly suggest an organic basis. To quote Light and coworkers (1929), "It has been our frequent experience to leave the wards with the firm conviction that these men are not organically sick, the whole picture being an emotional one, and that the viciousness attached to the picture could best be coped with in penal institutions. Just as frequently we have entered the ward and found these men suffering with violent muscle twitches, vomiting, perspiration and yawning and showing such a sickly appearance that we have been convinced that there must be an organic basis for their apparent suffering."

Therapy of Drug Addiction. The management of narcotic addiction is a highly specialized problem and only the broad outline can be given here. Combined medical, nursing and psychiatric therapy are essential for success. Withdrawal treatment is undertaken as a rule only by those with special training in this field. The patients are hospitalized or placed in special retreats which are available for this purpose. The Federal government maintains two hospitals for the study and management of narcotic addicts under the auspices of the United States Health Service, at Lexington, Kentucky, and at Fort Worth, Texas. It is to be hoped that other similar facilities will soon be provided.*

---

* The necessary information concerning voluntary admission of narcotic addicts to these two government hospitals can be obtained from the Surgeon General of the United States Public Health Service, Washington, D. C. Only citizens who are addicted to opium and coca leaves or their derivatives, or to peyote or Indian hemp are eligible. The cost for those who can pay is $1 per day. Confinement cannot be made without the patient's consent. Facilities for women are to be available early in 1940.

The patient is carefully examined to determine whether his physical condition is sufficiently good to warrant withdrawal therapy. Patients with renal, cardiac and other serious organic disease are poor risks, as are also pregnant women or debilitated persons. Careful search is made of all body orifices for contraband to insure that no smuggling of narcotics has been accomplished. Every conceivable scheme is used by confirmed addicts to insure a supply of opiate should the abstention symptoms prove too harsh. For example, they will have letters sent to them, the paper of which has been saturated with morphine, dried, ironed and inscribed with an innocent message; or the postage stamp may conceal the drug placed underneath (Light and associates, 1929). Therapy is especially difficult in those who are also addicted to alcohol or cocaine as well as to opiates.

Withdrawal may be abrupt, rapid or slow. Gradual withdrawal is probably less rigorous in those individuals who are not particularly robust. There is no such thing as a gradual reduction of dosage which will be imperceptible to the patient. A dose is soon reached below which craving and other symptoms appear. One can, however, reduce the dose far below the customary one used by the addict before craving is noted. This lower level is usually around 30 mgm regardless of the fact that much larger amounts were taken. When doses below 30 mgm are given, the patient becomes difficult to manage. Regardless of the method selected, symptoms do not occur in full force until several hours after the last dose of drug has been administered and then they continue to increase in severity for the next three days.

In addition to careful nursing, the patient should receive sedatives to promote sleep. Chloral hydrate is one of the most satisfactory for this purpose but the barbiturates and bromides may also be used. The taking of fluid and food should be encouraged. The belladonna alkaloids, atropine and scopolamine, have been widely employed in large doses in an attempt to mitigate the abstinence symptoms not only by central depression and amnesia but also by depression of structures innervated by cholinergic nerves, especially the bowel and secretory glands. Those advising the use of belladonna drugs believe that the distress of withdrawal is largely due to excessive stimulation of the vegetative nervous system. Comparative clinical studies by Lambert (1931), however, cast considerable doubt on the value of atropine and scopolamine. These agents tend to lessen the gastro-intestional symptoms but appear to aggravate many others. Exercise and warm baths tend to promote sleep, and nitrites may aid in the relief of muscle cramps.

Several routine systems of treatment exist and bear the names of their initiators such

TABLE 11

COMPARISON OF RESULTS OBTAINED IN THE ADDICT UPON WITHDRAWAL OF MORPHINE AND OF CERTAIN DERIVATIVES OF MORPHINE PREVIOUSLY SUBSTITUTED FOR IT

(Arranged from the data presented by Himmelsbach, Eddy, and associates, 1938)

DRUG	NO. OF CASES	NO. OF DAYS OF COMPLETE SUBSTITUTION FOR MORPHINE	DOSAGE OF SUBSTITUTED DRUG			ADEQUACY OF ADDICTION SATISFACTION BY SUBSTITUTED DRUG	ABSTINENCE SYNDROME FOLLOWING WITHDRAWAL OF SUBSTITUTED DRUG		
			No. of injections per day	Duration of dependence satisfaction	Daily amount in relation to morphine **		Onset	Intensity in relation to morphine	Duration ‡
				(hours)			(hours)		(days)
Morphine	±100	....	4	±6	....	....	±14	....	±8
Codeine	7	8 to 14	4	6 or more	±5	Adequate †	±20	As severe	±8
Dihydromorphinone (Dilaudid)	7	12 to 17	4 *	±3	±0.25 *	Complete	±10	As severe	±5
Methydihydromorphinone	7	7 to 10	8 or 9	±2	±0.2	Complete	± 3	As severe	5 to 7

* A sufficient dose of dilaudid was given so that not more than four injections daily were necessary. Smaller doses satisfied dependence for not much longer than three hours.

† Satisfaction of dependence, that is the relief of physiological disturbances and the disappearance of pains, aches, etc., was accomplished by substitution of codeine for morphine; but psychical manifestations of abstinence were not completely relieved. The patients were not as emotionally content on codeine as on morphine and claimed that there was "something missing."

‡ Number of days before the severe symptoms of the abstinence syndrome were spent. Return to normality required many weeks or several months.

** The actual amounts of drug used are not shown but rather the average amount needed per day by the group as a whole, in order to maintain psychic and physiological stability, in relation to the average amount of morphine required by that group prior to the substitution.

as the Pettey (1909), Lambert-Towns (1909) and Sceleth (1916) methods. They have in common the free use of intense purging and full doses of belladonna alkaloids. All these systems are successful but it is perhaps best to adapt the treatment to meet the needs of the individual patient.

Codeine substitution was thought for a time to afford a better therapy than any so far devised (Lambert, 1931). In brief, it consists in the withdrawal of morphine at the rate of 10 per cent per day over a period of ten days, and the substitution of ascending doses of codeine for the morphine. The dose of the substituted alkaloid starts at 30 mgm every four hours and is increased daily until the largest dose of codeine to be given is reached on the fifth day, 300 mgm every four hours. Codeine is continued at this dose level until three days after the last dose of morphine, and then it is decreased in amount as rapidly as the discomfort of the patient permits. It has been claimed that patients suffer little under this regimen and are quite manageable. Withdrawal from morphine by means of codeine substitution, however, probably has no distinct advantages. Indeed, reference to Table 11 indicates that withdrawal from the substituted codeine requires as long a period and is just as severe as withdrawal from morphine. Furthermore, the patient while on codeine does not experience relief of psychical manifestations of abstinence.

From time to time, various cures are advanced for morphine addiction or the therapy of withdrawal symptoms. "Narcosan" and sodium thiocyanate are two such proposals which have been entirely discredited. Insulin has also been recommended for addiction therapy but evidence of its value or rationale is meager.

After withdrawal symptoms have disappeared, rehabilitation of the patient is necessary to insure success of the cure. Wide personality and environmental adjustments are often required to remove the basic cause of the addiction. Cures are often temporary and the relapse rate, especially among confirmed addicts, is high. Great care should always be observed in using any opiate in a patient formerly addicted to narcotics. The treatment of addiction to heroine, dilaudid, cocaine and alcohol follows the general plan outlined.

For many of the facts and views on the important medical and social problems of narcotic addiction, the interested reader is referred to the books by Terry and Pellens (1928), Light and co-authors (1929), and Small and associates (1938).

Therapeutic Uses of Opium and Its Alkaloids

Sydenham, whose appraisal of opium is given at the opening of this discussion, also remarked that without opium few physicians would be sufficiently callous to practice therapeutics. Osler frequently referred to morphine as "God's own medicine." These statements serve to emphasize the *indispensable* nature of opium alkaloids, especially for the relief of pain. However, the fact that morphine and its derivatives are capable of causing addiction is a serious drawback and the physician must constantly be on guard lest his patient become addicted to the opiates.

There are a few simple procedures which will greatly decrease the likelihood of addiction. The physician should never employ a narcotic when another drug will accomplish the same end. In other words, morphine and its congeners are reserved only for certain definite indispensable uses which will be outlined. The patient is not to be informed of the fact that he is receiving an opiate. The hypodermic use of morphine is never to be entrusted to the patient himself. When a supply of narcotic is prescribed, it is made sufficient to last only until the patient is next seen by the physician, and this should be a short interval. The opiate is to be discontinued at the earliest possible moment. If the patient has received the drug for several days, he must be watched closely after cessation of therapy to discover whether he is addicted. In prescribing and dispensing of narcotics, it is incumbent upon the physician to be fully acquainted with the Federal and state laws regulating this field. These are briefly summarized on page 1324.

In using opiates, it is to be remembered that symptomatic therapy alone is being administered and that the underlying pathology is still present. Also the depressant actions of opium alkaloids may obscure the symptoms or progress of the disease, especially if the drugs are used unwisely. The proper employment of these agents, nevertheless, is of great assistance to the practitioner in performing his chief duty, namely, the relief of pain and suffering.

Certain aspects of the therapeutics of opium alkaloids have already been discussed. The uses of papaverine have been presented. The clinical differences between morphine, codeine, heroine and dilaudid in regard to pain, euphoria, depression and duration of action have been described; certain other clinical features of codeine, heroine, pantopon, and dilaudid have also been mentioned. The idiosyncrasies and variations in response to opium alkaloids have likewise been outlined.

Local Uses of Opiates. With the exception of the local application of dionine to the conjunctiva for the therapeutic hyperemia it produces, there are no rational local uses of opium alkaloids. These drugs are not local anesthetics and they relieve pain only by their central actions. Indeed, irritation and vesication may result from opium plasters, ointment or washes applied to the skin or mucosa.

Sudorific Action. Although morphine produces some degree of sweating, it is a very poor diaphoretic when compared with pilocarpine. The sweating caused by Dover's powder is mainly due to the ipecac content. The use of this powder as a diaphoretic for aborting the onset of "colds" due to exposure has the same rationale as suggested under alcohol.

Pain. *The opium alkaloids have no rival for the relief of pain,* and when suffering cannot be allayed by non-narcotic analgesics or other therapeutic measures, morphine may be considered indispensable. The types of pain obtunded most readily by morphine have already been discussed. This pain may arise directly from smooth muscle or nerve tissue or indirectly through traumatic, infectious or inflammatory processes. It bears re-emphasis that the analgesic action of this alkaloid is so specific that pain can often be considerably relieved by doses (five to 10 mgm) which cause little stupefaction or respiratory depression. All too frequently amounts are prescribed which produce unnecessary depression or sleep rather than specific analgesia. In this regard, dilaudid apparently has an advantage over morphine. In some cases in which dilaudid is used to abolish pain, it may be necessary to prescribe a sedative drug in addition if sleep is also desired. When both analgesia and sleep are required, morphine has no equal.

Pain from all parts of the body is dulled by the central action of the morphine alkaloids. The more severe the pain, the larger is the dose of opiate required and the greater the amount of drug that can be tolerated. Thus for the severe pain of coronary thrombosis, two to four times the usual therapeutic dose of morphine may be given without danger of seriously embarrassing the respiration. This is in keeping with the general principle that the degree of stupefaction caused by a given amount of a depressant drug is directly proportional to the level of reflex excitability of the nervous system. It is not unusual to administer within an hour from 45 to 60 mgm of morphine in divided portions for patients with excruciating pain. However, caution is required in the administration of these large total doses, especially when they are used for severe pain of a type which may suddenly lessen in severity or even disappear entirely. For example, the pain of coronary occlusion or of renal or biliary colic may rapidly decline spontaneously. If the patient has been given a large amount of morphine, he may show signs of morphine poisoning. Close observation of the patient and proper spacing of the doses of morphine will usually prevent such an occurrence.

Pain is a chief diagnostic sign for the physician and its total abolition may seriously handicap the discovery of the nature of the patient's illness. It has been said of morphine that, "It not only puts the patient to sleep but also puts the physician to sleep." While it is generally unwarranted to make the diagnosis at the expense of unbearable pain, nevertheless there are certain conditions in which opiates are not usually prescribed until the diagnosis has been made and the permission obtained for operation, should the latter be necessary. These conditions especially comprise what is known as the *acute surgical abdomen.* For example, no single cause, other than the use of a cathartic, is responsible for more complications or deaths from acute appendicitis than the misuse of opiates.

Nevertheless, it has been claimed that the skillful use of morphine may sometimes aid considerably in the diagnosis of acute abdominal conditions. The patient who is restless, apprehensive and in severe pain often cannot give a satisfactory or correct history. Rigidity of the abdominal muscles may prevent an adequate physical examination. This rigidity may be due not only to the reflex spinal component as a result of an inflamed viscus but also to a cortical component secondary to intense pain. Morphine in analgesic doses abolishes the cortical component and leaves the spinal reflexes unaffected (Zierold, 1935). Morphine, in expert hands, may thus be employed to aid in abdominal diagnosis, for which purpose it has been injected intravenously (15 mgm) to obtain analgesia and cooperation quickly (Singer, 1936). Naturally, a base line history and physical examination are necessary and the patient must be followed closely.

In patients with pain due to *neoplastic growths* or chronic hopeless diseases, the use of morphine alkaloids should be reserved until non-narcotic drugs no longer give relief. Then codeine should be employed in combination with non-narcotic sedatives and analgesics and the doses increased until pain can no longer be controlled without morphine or dilaudid. The doses should be kept as low as possible so that maximal relief may be given for the longest possible period. Tolerance develops and one wishes to reserve a margin of susceptibility in order to cope with the terminal stages when pain may be excruciating. In other words, "The physician should use morphine as a miser spends his gold." If necessary, of course, morphine is given without stint. Addiction is expected and justifiable in patients with malignant growths. When opiates are unsatisfactory, nerve blocking by injections of alcohol or chordotomy may be required if the nature of the lesion allows. In most cases the euphoria, tranquillity and relief of pain afforded by the wise use of narcotics are a blessing to the patient and his family and death is made easy and comfortable.

For the relief of pain arising from spasm of smooth muscle, as in *renal or biliary colic,* morphine has no equal. Other measures including antispasmodics such as atropine, nitrites and heat may be employed first, but if they are ineffective opiates must be used. Morphine is also indispensable for the relief of pain due to *acute vascular occlusion* whether this be peripheral, pulmonary or coronary in origin. Papaverine may be given advantageously in embolism of peripheral or pulmonary arteries. In painful acute *pericarditis, pleurisy* and spontaneous *pneumothorax,* morphine is likewise indicated. Carefully chosen and properly spaced doses of codeine or morphine may occasionally be necessary in *pneumonia* to control pain, dyspnea and restlessness. Traumatic pain arising from *fractures, burns,* etc. frequently requires morphine, and *shock* whether due to trauma or poisons often necessitates the administration of opiates not only to relieve pain but also to control restlessness and to allow sleep.

The use of opiates in *obstetrical analgesia* is a highly specialized field requiring considerable experience and sound judgment to insure safety. Morphine has been combined with scopolamine in "twilight sleep" but this mixture is not used nearly as much as formerly. Various combinations of barbiturates, scopolamine, paraldehyde and the inhalation anesthetics have made morphine less popular in obstetrical work. The opiates are powerful respiratory depressants. The fetus is especially susceptible to morphine which greatly increases the incidence of asphyxia in the newborn. The use and value of morphine in *preanesthetic medication* are fully presented elsewhere (page 46). Post-operatively, narcotics may be employed to control pain and discomfort for the first one to three days, but if prescribed indiscriminately they may obscure the outcome of surgery and the course of recovery, as well as prevent the early recognition of complications. For *headache,* codeine may be effectively combined with analgesics like salicylates or acetanilid. Morphine is not used in migraine unless all other measures, including ergotamine, have failed. Great care should be exercised to prevent addiction.

Sedation and Sleep. Whenever possible, drugs other than narcotics are to be prescribed for sedation, tranquillity or sleep. In many cases, however, the opiates must be resorted to in order to provide the necessary relief from insomnia, restlessness or excitement and thus conserve the patient's strength. The ordinary nonnarcotic somnifacients such as bromides, chloral hydrate and barbiturates are not analgesic and when sleeplessness is due to *pain* or *cough,* opiates are often required. In certain forms of *delirium, mania,* and *psychoses* and in the hyperexcitable states caused by *thyrotoxicosis* and certain *encephalopathies,* opium alkaloids may be needed. In these conditions smaller doses of morphine produce sedation than are necessary when pain is also present. When sleep and relief from restlessness and apprehension are absolutely essential as in *threatened abortion, internal hemorrhage, congestive heart failure* and *massive pulmonary hemorrhage,* morphine provides a valuable therapeutic agent.

Cough and Dyspnea. *Cough,* especially when unproductive and irritating, interferes with rest and sleep and may be painful. It can also result in cardiac strain and cause pulmonary or cardiovascular accidents. The types, mechanism and physiological usefulness of coughing are presented elsewhere (page 815). The opiates comprise the so-called anodyne expectorants, and codeine in particular deserves preference for quieting an overactive cough reflex. The antitussive dose is kept small (five to 10 mgm) because repeated medication may be necessary. The uniformly effective oral dose of codeine for cough is about 10 mgm (Davenport, 1938). Large doses of codeine (over 60 mgm) may actually increase the irritability of the respiratory and cough mechanism. Codeine can be effectively incorporated in an expectorant cough mixture for a dry, irritating cough with the object of stimulating secretion of mucus and yet reserving the cough reflex for productive expectoration. Coughing should not be unnecessarily depressed, especially if bronchial secretion is profuse, because drainage will then be insufficient and complications may ensue. Small amounts of codeine, or of morphine (two to four mgm), will decrease the frequency of coughing without altering significantly the respiratory minute volume.

Certain forms of *dyspnea* yield only to opiates. Especially in this category is the dyspnea of acute left ventricular failure and pulmonary edema. In *bronchial asthma,* morphine is not indicated because of the danger of addiction, because morphine tends to depress respiration and constrict bronchioles, and due to the fact that asthmatics may be allergic to the drug. Death may occur from its use in asthma.

There is no good evidence that the use of codeine or papaverine shortens the duration of the "common cold." Opiates tend to dry the mucosal lining of the throat and nose but other measures such as atropine can accomplish this end. If headache and pain require relief, non-narcotic analgesics should first be employed. If the symptomatic improvement afforded by codeine encourages the patient to be ambulatory when he should be in bed, the medication has done harm by increasing the chances for complications and the infection of other individuals.

Antiperistaltic Action. The action of the opium alkaloids in checking peristalsis and causing constipation is desired in a variety of diseases and syndromes. These include exhausting diarrheas and dysenteries, gastro-intestinal hemorrhage, perforation or rupture of abdominal viscera, peritonitis, and rectal tenesmus. Where diarrhea is caused by acute food or drug poisoning, opiates are not prescribed until the offending agent has been evacuated by saline cathartics. Traditionally opium preparations rather than the alkaloids are prescribed, either the tincture (0.5 to 1.0 cc) or the powder (30 to 100 mgm) being used.

Anticonvulsant Action. The use of morphine in convulsive disorders such as strychnine poisoning, tetanus, status epilepticus, etc. is invalid and preference should be given to the soluble barbiturates, paraldehyde and chloral hydrate. The motor excitability of the cortex is depressed only by large doses of morphine which in turn cause an increase in reflex excitability of the spinal cord. Morphine sulfate, however, is given in conjunction with chloral hydrate in the Stroganoff therapy for impending eclamptic convulsions, two doses of morphine (15 mgm) being injected at an interval of four hours.

CHAPTER 13

ANALGESICS AND ANTIPYRETICS

I. THE SALICYLATES, CINCHOPHEN AND NEOCINCHOPHEN

The growing scarcity and the consequent high price of quinine during the last third of the 19th century motivated the search for synthetic substitutes. As a result, a large number of compounds were introduced into medicine and, although they differed considerably from quinine both chemically and in their lack of antimalarial efficacy, they shared with cinchona the ability to produce antipyresis and analgesia. Several have survived and proved their usefulness, not so much as antipyretics but rather as analgesics. They are also useful in the treatment of acute rheumatic fever and gout.

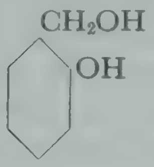
The analgesic-antipyretic drugs may be divided into three classes, as follows:

I. The salicylate-cinchophen group.
II. The paraminophenol derivatives—acetanilid and acetophenetidin.
III. The pyrazolon derivatives—antipyrine and aminopyrine.

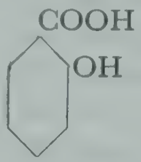
THE SALICYLATES

History and Source. *Willow bark (Salix alba),* the antipyretic property of which was known to the ancients, yields a bitter glycoside called *salicin,* first discovered by Leroux in 1827. On hydrolysis, salicin liberates glucose and *salicylic alcohol* (saligenin). Piria, in 1838, made *salicylic acid* from salicin. Six years later, salicylic acid was prepared from *oil of gaultheria* (oil of wintergreen) by Cahours. The synthetic manufacture of this acid from phenol was accomplished in 1860 by Kolbe and Lautemann. *Sodium salicylate* was used for the first time as an antipyretic by Buss in 1875, and in the following year its value in *rheumatic fever* was discovered by Stricker. *Phenylsalicylate* was introduced into medicine in 1886 by Nencki, and *acetylsalicylic acid* (aspirin) in 1899 by Dreser. The name aspirin comes from "spirsäure," the German word for salicylic acid. The synthetic salicylates soon completely displaced the more expensive compounds obtained from natural sources, being just as effective.

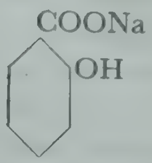
Chemistry. Salicylic acid (orthohydroxybenzoic acid) is so irritating that it can only be used externally and therefore various derivatives of this acid have been synthesized for systemic use. These may be grouped in two large classes—those which are *esters of salicylic acid* through substitution of the H in the carboxyl group, and those which are *salicylate esters of organic acids* in which the carboxyl group of salicylic acid is retained and substitution is made in the OH group. For example, aspirin is an ester of acetic acid. In addition, there are simple salts of salicylic acid such as the sodium and ammonium salts. These relations can be seen clearly from the following structural formulas:



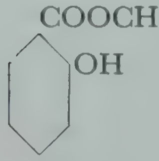
Salicylic Alcohol
(Saligenin)



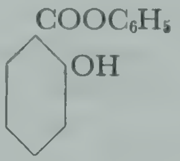
Salicylic Acid



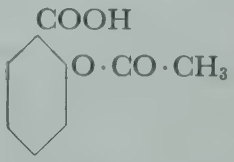
Sodium Salicylate



Methyl Salicylate
(Oil of Wintergreen)



Phenyl Salicylate



Acetylsalicylic Acid
(Aspirin)

All the above compounds are referred to collectively as the "salicylates" or the "salicyl" drugs. The salicylates will be discussed as a group, and major differences noted as occasion arises.

Relationship Between Chemical Structure and Action. Salicylates exert their typical effects by virtue of their salicylic acid content. Variations in solubility and propensity to cause local irritation are the main factors which determine the degree of usefulness of these chemicals. The ortho position of the OH is an important feature for the action of salicylate. Benzoic acid, C_6H_5COOH, shares many of the actions of salicylic acid but is much weaker. If a methyl group is added to the benzene ring of salicylic acid, *cresotinic acid* ($C_6H_3{\cdot}CH_3{\cdot}OH{\cdot}COOH$) is formed. At one time it was claimed, especially by the interested manufacturers of the more expensive natural salicylates, that cresotinic acid was a toxic contaminant in synthetic salicylates. Conclusive researches demonstrated that cresotinic acid was no more toxic than salicylic acid and did not "contaminate" synthetic salicylates. The efficacy of the different salicylates depends in part on the amount of salicylate liberated in the body, but not entirely on this factor. For example, the salicylic acid equivalents of the commonly used drugs in this group are within 10 per cent of each other and yet the therapeutic potency of acetylsalicylic acid and methyl salicylate is about 50 per cent greater than sodium salicylate. This also holds true for their toxicities and depends especially on factors of solubility.

Pharmacological Actions

Local. *Antiseptic Action.* The salicylates, especially salicylic acid, are weakly *bacteriostatic.* In this respect, their action resembles that of quinine and benzoic acid in that certain fermentation processes are inhibited, the growth of moulds and fungi is checked, the putrefaction of meat, urine and other substances is delayed, and unicellular organisms and leukocytes are paralyzed. In alkaline media, phenyl salicylate may have more pronounced effects due to the liberation of phenol.

Local Irritant Effects. Salicylic acid is quite irritating to skin and mucosa, and destroys epithelial cells. The keratolytic action of the free acid is employed for the local treatment of warts, corns, fungus infections and certain types of eczematous dermatitis. The tissue cells swell, soften and desquamate. The salts of salicylic acid are innocuous to the unbroken skin, but by release of the free acid the gastric mucosa may be irritated. Methyl salicylate (oil of wintergreen) is irritant both to the skin and gastric mucosa, and is used externally in liniments as a counterirritant.

Central Nervous System. *Antipyresis.* Salicylates lower body temperature. This action is usually rapid and effective in febrile patients, but is rarely demonstrable when the temperature is normal (Figure 21). This is the rule for most antipyretics. Normal regulation of body heat requires a delicate balance between heat production and heat loss (DuBois, 1936, 1937). The central nervous system, especially hypothalamic nuclei, plays an indispensable rôle in regulating the peripheral mechanisms concerned with the production and loss of body heat. Consequently, the hypothalamus has been termed the "thermostat" of the body. In fever, the balance between heat production and heat loss still persists except that the "thermostat" is set at a higher level. The salicylates act to reset the "thermostat" for normal temperature. Heat production is not inhibited but heat dissipation is augmented by increased peripheral blood flow and sweating. There is abundant evidence to show that the salicylates act mainly on the central nervous system and not peripherally on blood vessels or sweat glands. High section of the spinal cord prevents the antipyretic drugs from lowering the temperature of fevered animals. Sweating is so prominently associated with the use of salicylates that it has come to be looked upon as a major response. Marked sweating, however, does not occur unless there is fever, and the latter can be lowered with salicylates even if sweating is prevented by atropine. The salicylates also cause hydration of the blood (Barbour, 1921) and this facilitates both sweating and the radiation of heat. The metabolic rate and the respiratory quotient in normal persons are not directly altered even by large doses of salicylates. Heat production is therefore not depressed. In febrile patients, the metabolic rate is lowered by antipyretic drugs but this is consequent to the fall in temperature. (The metabolic rate increases seven per cent for every degree F. of fever.) The mechanism of antipyresis summarized here

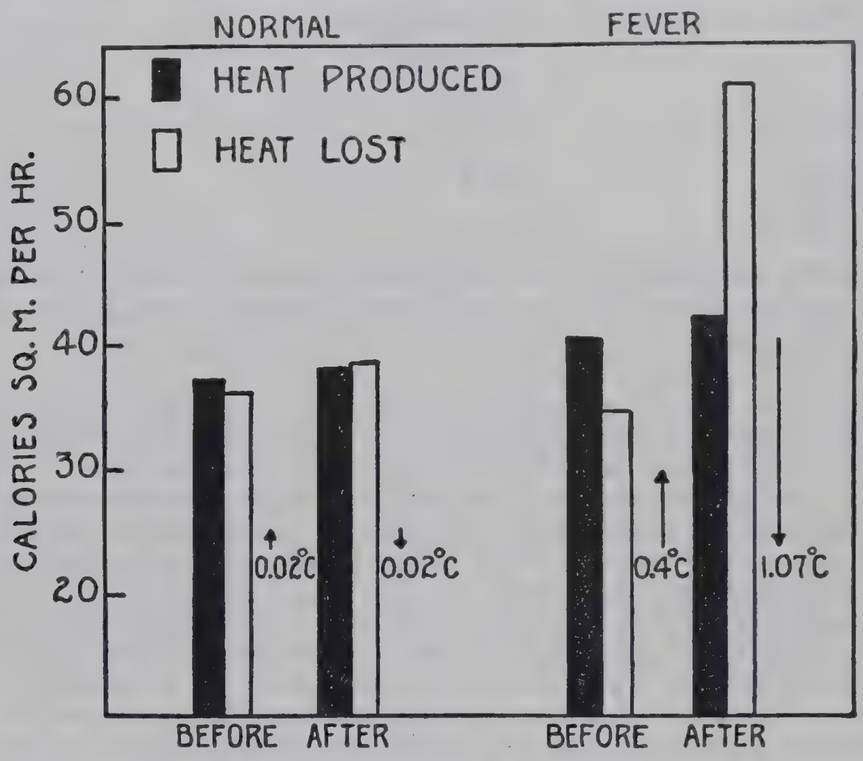


FIGURE 21. *The antipyretic effect of one gram of acetylsalicylic acid in normal persons and patients with fever.*

Arrow indicates direction and relative degree of temperature change. Note the insignificant antipyretic response in the normal person as compared with the febrile patient. Observe that the mechanism of antipyresis is an increased elimination rather than a decreased production of heat. (Figure constructed from the data of Barbour and Devenis, 1919, and Barbour, 1919.)

for the salicylates likewise applies to acetanilid, acetophenetidin, antipyrine and aminopyrine.

Analgesia. The salicylates are capable of alleviating certain types of pain. This is probably due to a central depressant action located in the optic thalami. That the site of action is not cortical is indicated by the fact that analgesic doses of the salicylates cause no mental disturbance, anesthesia or changes in modalities of sensation other than pain sense. Although some individuals claim to experience a mild hypnotic effect, this is certainly unusual and may be due to psychic factors. The types of pain amenable to relief by salicylates are headache, myalgia, arthralgia and other pains arising from integumental structures rather than from viscera. The significance of this is poorly understood. The salicylates are much inferior to morphine as analgesics. For example, the threshold for cutaneous pain as determined in human subjects by heat irradiation (Hardy, Wolff and Goodell, 1940) was increased only 35 per cent by 1.8 grams of aspirin taken orally, whereas an increase of 70 per cent was noted after 15 mgm of morphine sulfate administered intramuscularly (page 196).

Nerve endings are not anesthetized by salicylates, except saligenin (page 303). The relief obtained from the local application of methyl salicylate is due to the counterirritation. The use of aspirin locally for alleviating dental pain or sore throat has no rational basis.

Respiration. Average clinical doses of salicylates do not affect breathing, but toxic amounts first accelerate and deepen and finally depress respiration. In hypersensitive patients, the salicylates may cause dyspnea by precipitating an asthmatic attack.

Other Central Actions. In high doses, the salicylates have a toxic action on the central nervous system, consisting of stimulation followed by depression. The effects are similar to but milder than those produced by phenol, and are described under salicylate poisoning.

Cardiovascular System. Ordinary therapeutic doses of salicylates have no important cardiovascular actions. The peripheral vessels tend to relax with large doses, due to a direct effect on the smooth muscle of blood vessels. Toxic amounts depress the circulation directly and by central vasomotor paralysis. The concentrations necessary to injure the perfused heart are much higher than are obtainable in man even with toxic doses. There is no clinical or experimental evidence to support the opinion that the salicylates, especially aspirin, are injurious to the heart.

Gastro-intestinal Actions. The irritant effects of salicylates on the gastric mucosa may result in epigastric distress, nausea and vomiting. Large doses have been reported to cause stomach ulcerations in experimental animals, and melena has been observed from the use of aspirin in human beings (Hurst and Lintott, 1939). Vomiting after toxic doses of salicylates is not only due to local irritation but also to a central emetic action. Acetylsalicylic acid is less irritating to the stomach than is sodium salicylate, probably because it is relatively insoluble.

The salicylates cause an increase in the volume output of bile, but a decrease in the total cholate excretion (Schmidt and coworkers, 1938). This *choleretic action* is apparently due to a direct effect on liver cells. However, the experimental work in this field is contradictory and offers too insecure a basis for the clinical use of these agents as choleretics.

Metabolic Actions. *Uric Acid.* A prominent effect of therapeutic doses of salicylates, and especially of cinchophen, is to increase the urinary excretion of uric acid. The increase may be 30 per cent to 50 per cent, but is occasionally as much as 100 per cent. The blood uric acid is concomitantly reduced to one-third of its original level, although this is not invariably the case, for occasionally the blood uric acid may be elevated during the period of increased urinary excretion. Both the endogenous and exogenous uric acid fractions are affected, because the urinary changes occur in patients on purine-free diets as well as on high purine diets, and also the excretion of injected uric acid is hastened. The other constituents of the urine apparently are not simultaneously altered, so that the effect on uric acid excretion seems to be a specific one. If administration of the drug is stopped after a single dose or a few repeated doses, the uric acid excretion falls below the normal level and then rises slowly over a period of two to four days. Chronic administration may or may not be accompanied by a continuously elevated level of uric acid excretion, depending somewhat on the diet.

The mechanism by which the salicylates and cinchophen increase uric acid excretion is unknown. In general, three major theories have been advanced. The first explanation to be suggested was that the uric acid arose from disintegration of white blood cells. Careful clinical studies failed to support this view. The second theory proposes that these drugs increase uric acid formation or mobilization, as for example, by increased destruction of nucleoproteins, enhanced conversion from purines, inhibition of an uricolytic ferment, or mobilization of preformed uric acid from storage depots. The third theory maintains that the renal threshold for the purine is lowered. Presumably, the tubular reabsorption of uric acid is inhibited by the drugs, and hence the urinary excretion rises and the blood level falls. The renal basis of the uricosuria, though very probable, is yet to be fully established, and accurate uric acid clearance studies would be most helpful. Observations unexplained by this theory are the increased blood uric acid levels which occasionally occur, the increased biliary excretion of uric acid, and the apparent stimulation of purine metabolism by these drugs.

For details of this problem, the interested reader is referred to Hanzlik (1927) and Grabfield and Pratt (1931).

Actions on the Blood. Full therapeutic doses of salicylates do not materially alter the *alkali reserve* or the *pH of the blood*. Toxic doses of salicyl compounds, however, present a clinical picture which resembles diabetic or renal acidosis. The air-hunger which often occurs is similar to Kussmaul's hyperpnea and has been called "salicyl dyspnea." The mechanism is not understood, but it is thought to be due to a direct stimulatory action of salicylates on the respiratory center. On the basis of signs and symptoms alone, it may be difficult or impossible to distinguish salicylate poisoning from diabetic acidosis and coma. However, the laboratory findings indicate that the blood sugar level and carbon dioxide-combining power of the serum are little changed in salicylate poisoning whereas the former is elevated and the latter is decreased in diabetic acidosis. However, hyperpnea from salicylates may result in a carbon dioxide loss and a compensatory excretion of fixed base in the urine. The urines in both instances may reduce copper solutions, due to the false positive test for sugar given by salicylates. The ferric chloride test for acetoacetic acid in the urine shows a violet color after salicylates and not a positive Burgundy red reaction. If severe kidney damage occurs from salicylates, a frank renal acidosis may follow.

The number of *red and white blood cells* is not significantly changed by salicylate medication. The mechanism of the salicylate depression of leukocytosis in acute rheumatic fever is not understood, but is of considerable importance in judging the progress of the disease. Methemoglobin is not produced by salicylates and agranulocytosis has not been reported from their use.

Renal Effects. Moderate doses of salicylates cause a slight diuresis but it is likely that this is merely a salt effect. Large doses of salicylates, such as those employed in acute rheumatic fever, may somewhat diminish urine output, partly due to increased sweating but also because of renal impairment (Scott and Hanzlik, 1916; Hanzlik, Scott and Reycraft, 1917). The increase in blood urea, decrease in phenolsulfonphthalein excretion and albuminuria all indicate kidney impairment. Albuminuria is a constant finding in man after about three grams of salicylates have been taken. Casts, leukocytes and occasionally red blood cells may also be found after large doses. These renal effects disappear quickly without residual damage upon cessation of salicylate medication. Histological evidence of nephritis has been obtained both experimentally in animals and in cases of human poisoning. The alleged protective effect of sodium bicarbonate upon these renal changes has been disproved (Hanzlik, 1927). In some patients, large doses of sodium salicylate may so diminish renal function and urine output that the body weight increases. This has been termed "salicyl edema" but actual pitting edema does not develop.

"Antirheumatic Actions." The salicylates reduce the pain, immobility, swelling and inflammation of the joints in acute rheumatic fever, and this constitutes a major therapeutic use of these drugs. So efficient are the salicylates in this respect that they have been employed as a therapeutic test in the differential diagnosis of arthritis. The salicyl compounds and cinchophen are qualitatively alike in this antirheumatic action. The cardiac lesions and other visceral involvement in rheumatic fever, such as pleuritis, peritonitis, encephalopathy, chorea, and subcutaneous nodules, are not beneficially affected. The course and complications of the disease are also not influenced.

The mechanism of the action of salicylates in acute rheumatic fever is poorly understood. There is no evidence that immune bodies are increased, that a bactericidal effect is operative, that the uricosuric action is involved or that the salicylates have a general antiphlogistic action. The numerous studies with salicylates in experimental arthritis in animals have yielded contradictory results and are not directly applicable to rheumatic fever in human beings. The mechanism by which salicylates reduce joint effusions in rheumatic fever still remains an enigma. That the salicylates are not specific is shown by the fact that aminopyrine and cinchophen have a similar action. It is difficult to believe that the entire benefit can be attributed to the antipyresis and analgesia, although these two actions are the chief ones shared in common by agents effective in rheumatic fever.

Absorption, Fate and Excretion. *Absorption.* The salicylates are readily absorbed from the gastro-intestinal tract, including the rectum, and other mucosal surfaces of the body. In fact, rapid absorption may occur from the stomach itself (Bradley, Schnedorf and Ivy, 1936). The esters are hydrolyzed to salicylic acid only to a limited extent in the stomach and intestine and are chiefly absorbed as such into the circulation. Salicylic acid is rapidly absorbed from the intact skin, especially when applied in lard or lanolin. Methyl salicylate is likewise absorbed when applied cutaneously, but this route is too uncertain when systemic effects are desired. Gastro-intestinal absorption of this ester may be delayed many hours and therefore gastric lavage should be performed in cases of poisoning even though they are seen late.

Distribution and Fate. Shortly after absorption, salicylate can be identified in nearly every tissue and fluid. It is also found in pathological fluids, but the joint effusions in rheumatic fever contain no higher concentration of salicylate than does the blood. Hence there is no selective distribution of the drug to account for its therapeutic action.

The claim that free salicylic acid exists in the body and exerts a bactericidal action has not been substantiated. No free salicylic acid can be demonstrated in body tissues or fluids and the pH necessary for liberation of the acid is far lower than can occur in the body.

Excretion. Salicylates are excreted from the body by all channels, but especially by the urine. The urine may appear greenish brown after salicylate medication. Salicylate can be detected in the urine within 10 to 15 minutes after administration of a full therapeutic dose. The major excretion occurs within a few hours, but traces appear in the urine for three days or longer. Acetylsalicylic acid and methyl salicylate require a longer period for complete excretion than does sodium salicylate. About 20 per cent of salicylate is destroyed in the tissues. In patients with rheumatic and other fevers, the fraction destroyed may increase to 30 or 40 per cent. Simultaneous administration of sodium bicarbonate does not hasten salicylate excretion.

The esters of salicylic acid are excreted in the urine in part unchanged, from 10 to 35 per cent of acetylsalicylic acid being eliminated as such. Also, the urine of patients receiving the methyl ester has the odor of oil of wintergreen. Some of the salicylate is found in the urine in conjugated form, as the glycuronate and sulfate. Some oxidation of salicylate probably also occurs.

Preparations, Doses and Routes of Administration. The two most commonly used preparations of salicylate for oral administration are sodium salicylate and acetylsalicylic acid.

Sodium Salicylate, U.S.P., B.P., is a white or faintly pink powder, which is odorless and has a sweet, saline taste. It is quite soluble in water (1:0.9).

Acetylsalicylic Acid (Aspirin), U.S.P., B.P., is a white crystalline odorless powder. In moist air, it gradually hydrolyzes to salicylic and acetic acids. It is rather insoluble in water (1:300).

Ammonium Salicylate, U.S.P., *Strontium Salicylate,* N.F. and *Lithium Salicylate,* N.F., have no advantages over the sodium salt and are practically obsolete. All three are white, crystalline, odorless powders, and the first two are extremely soluble in water.

Phenyl Salicylate (Salol), U.S.P., is a white crystalline powder, having an aromatic odor and a characteristic taste. It is practically insoluble in water (1:6670) but is readily hydrolyzed in the alkaline intestinal juices to phenol (40 per cent) and salicylic acid (60 per cent). The phenol is readily absorbed and may cause carbolic acid poisoning if large doses of the ester are administered.

Methyl Salicylate (Oil of Sweet Birch, Oil of Wintergreen, Oil of Gaultheria, Oil of Betula), U.S.P., B.P., is obtained synthetically or by steam distillation of the leaves of *Gaultheria procumbens* or from the bark of *Betula lenta.* It is a colorless, yellowish or reddish liquid, having the characteristic odor and taste of wintergreen. It is slightly soluble in water but is miscible with alcohol. Methyl salicylate is so irritating when given orally that it is employed only for cutaneous counterirritation in the form of salves and liniments. Its use in low concentrations as a flavoring agent is discussed elsewhere (page 1318).

Salicylic Acid, U.S.P., B.P., is a white crystalline powder, odorless and tasteless when prepared synthetically. It is rather insoluble in water (1:460) but quite soluble in alcohol (1:2.7) and organic solvents. The acid is so irritating to the gastrointestinal tract that its use is reserved for local application as a keratolytic agent. Salicylic acid is a component of many ointments, some of which are official, as for example, *Whitfield's Ointment,* N.F. (page 1312), *Compound Salicylic Collodion,* N.F. (10 per cent salicylic acid in flexible collodion), *Paste of Zinc Oxide with Salicylic Acid* (page 861), N.F. and *Ointment of Salicylic Acid,* B.P. (two per cent of the acid in white paraffin ointment).

Several esters of salicylic acid other than the official ones already described are available but rarely used. They have no advantages over sodium salicylate and aspirin. Some of these are as follows: *Salysal*, N.N.R., the salicylic ester of salicylic acid; *Novaspirin*, N.N.R., methylene-citrylsalicylic acid; *Ethyl Salicylate*, N.N.R.; *Sal-Ethyl Carbonate*, N.N.R., the carbonic acid ester of ethyl salicylate.

The *dose* of the salicylates depends on the condition being treated. The usual dose of sodium salicylate or acetylsalicylic acid is from 0.3 to 1.0 gram (five to 15 grains). This may be repeated every three or four hours. In acute rheumatic fever, in contrast, intensive medication is employed and 1.0 gram or more of a salicylate is given every hour until early toxic effects ensue. Children are quite tolerant of the salicylates and require larger doses than calculated by their age or weight.

The *route of administration* is practically always oral. There is no advantage in and rarely a necessity for giving them parenterally. The intravenous use of these drugs is unjustified and dangerous. The only valid intravenous use of salicylates is in local varicosities for the purpose of sclerosing veins. Occasionally, the rectal administration of sodium salicylate (two per cent) in thin starch or acacia solution may be necessary in infants or when oral medication is not retained.

Nausea and gastric irritation from sodium salicylate may be avoided by the simultaneous administration of an equal or double amount of *sodium bicarbonate*. This protects against the release of salicylic acid. Alkali is not so necessary with acetylsalicylic acid, but the former opinion that sodium bicarbonate may increase the irritation from aspirin is not substantiated by clinical experience or laboratory experimentation (Schnedorf, Bradley and Ivy, 1936). Salicylates are conveniently taken in tablets or capsules rather than in solutions. Solutions of the sodium salt have a sweetish, nauseant taste which is difficult to mask completely. They also become discolored on standing and form a black precipitate if bicarbonate is present. Acetylsalicylic acid is quite insoluble, has many chemical incompatibilities, and is unstable in watery suspensions. It should therefore be prescribed alone in solid dry form.

Toxicology. The wide use of salicylates in medicine and their indiscriminate employment by the laity for every conceivable ailment provide the basis for numerous instances of toxic reactions. Fortunately, most of these poisonings are mild. Serious intoxication, however, does occur. In more than 30 reported cases in the eight year period following 1928, 50 per cent died (Bowen, Ronfa and Clinger, 1936). Balazs (1930), however, has reported that among 752 attempts at suicide with acetylsalicylic acid, only four ended fatally. *Idiosyncrasy* is also a cause of untoward response to the salicylates. Furthermore, the presence of renal impairment enhances the possibility of salicylate poisoning. As little as three grams of salicylate a day may cause severe intoxication in nephritic patients.

Acute Salicylate Poisoning. All the salicylates except salol cause the same type of intoxication. The *fatal dose* varies with the preparation. From 10 to 30 grams of sodium salicylate have caused death in adults but larger amounts have been ingested without fatal results. The fatal doses of acetylsalicylic acid and methyl salicylate are less than that of the sodium salt. As little as six cc of methyl salicylate may be fatal for children. In acute rheumatic fever, doses of salicylate are used which border on the toxic and under these conditions one expects to encounter early symptoms of poisoning.

Symptoms. Mild salicylate intoxication is termed "salicylism." This condition resembles cinchonism very closely, and is observed as a rule only when large doses are given repeatedly. When fully developed, the syndrome consists of headache, dizziness, ringing in the ears, difficulty in hearing, dimness of vision, mental confusion, sweating, thirst, nausea, vomiting, and diarrhea. The mechanisms of the auditory and the visual disturbances are the same as those described under quinine. The pulse and respiration may be accelerated, and there may also be skin reactions of an erythematous, scarlatiniform, pruritic, eczematoid, or desquamative character. Rarely, the cutaneous lesions may be bullous or purpuric in nature, and hemorrhages may occur from mucous membranes. Fever may be prominent, especially in children. Symptoms of central excitation are sometimes prominent in salicylate poisoning and resemble those caused by atropine. This stimulation has been called the "salicylic jag" and is characterized by restlessness, incoherent speech, excitement and occasionally mania, delirium and hallucinations. All the effects mentioned may occur when approximately 12 grams of salicylate have been given in divided doses over a period of 12 to 24 hours and disappear quickly when medication ceases.

Larger amounts of salicylates may cause disturbances in respiration referred to previously as "salicyl dyspnea" with a clinical picture resembling diabetic or renal acidosis. The kidney changes that occur after toxic amounts of salicylates have already been described. As poisoning progresses, central stimulation is replaced by increasing depression, stupor and coma. Cardiovascular collapse and respiratory depression ensue, and terminal asphyxial convulsions sometimes appear. Death usually results from respiratory failure after a period of unconsciousness.

Symptoms of poisoning by *oil of wintergreen* do not differ essentially from those just described. Poisoning occurs most frequently in children who mistake this aromatic oil for candy, and central nervous system symptoms and hyperpyrexia are prominent features. The odor of the drug can easily be detected in the urine and vomitus. Methyl salicylate should always be kept where children cannot gain access to it. Of 43 cases of poisoning in children reviewed by Stevenson (1937), 59 per cent were fatal. Poisoning by *salicylic acid* differs only in the prominent gastro-intestinal symptoms due to the marked local irritation. *Phenyl salicylate* poisoning is unique in that the most prominent symptoms are due to phenol which is liberated by hydrolysis in the intestinal tract.

Idiosyncrasy. Idiosyncrasy to salicylates manifests itself usually in the form of skin rashes and anaphylactic phenomena. These reactions are due to unexplained hypersensitivity and may occur after the first administration of a small dose of salicylate. However, the fact that one has been able to take salicylate without ill effects is no guaranty against the occurrence of allergic reactions to the drug. Acetylsalicylic acid is the compound most often involved. The skin lesions have already been described, and are frequently urticarial in nature. Allergic responses take the form of angioneurotic edema or asthma. If laryngeal swelling occurs, alarming asphyxial symptoms may develop. Edema of the eyelids, tongue, lips, face and intestinal tract is not uncommon and an erysipelatous swelling of the entire face may occur. Most of the patients who react badly to aspirin have a history of allergic disease, especially asthma. Over two-thirds of the allergic reactions to acetylsalicylic acid are due to asthma, and death may occur. One should therefore observe care in prescribing aspirin for patients with asthma, especially if they also have nasal polyps (Prickman and Buchstein, 1937). Individuals with idiosyncrasy to aspirin should be told of this fact and warned against taking patent medicines which often contain this drug. The skin tests are of no value in anticipating hypersensitivity, and may even provoke a severe reaction in some patients.

Treatment. The treatment of salicylate poisoning is purely symptomatic. Gastric lavage is performed to remove any poison still in the stomach, and magnesium sulfate is given to hasten unabsorbed salicylate through the intestinal canal. Fever may be counteracted by alcohol sponges. A liberal supply of fluid and sodium chloride is essential to offset the loss through vomiting, diarrhea and sweating. Intravenous solutions of hypertonic glucose are helpful in supporting the circulation, and therapy for shock is to be instituted if the shock syndrome intervenes. When cerebral excitement is prominent, small doses of sedatives may be needed. When the poisoning has advanced to the stage of central depression, stimulants such as caffeine and ephedrine may be required. Epinephrine is the drug of choice in treatment of allergic manifestations and it usually controls urticaria and angioneurotic edema without difficulty. On the other hand, asthma due to acetylsalicylic acid may at times prove most refractory to therapy.

Clinical Uses of the Salicylates

There are many local and systemic uses of the salicylates. Several of these are dictated by tradition and empirical results rather than by a clear understanding of the mechanism of therapeutic relief. The majority of the properties attributed to salicylates by the laity and for which they are widely used have no existence in fact.

Local Uses. *Salicylic acid* is employed only externally. It is incorporated in a concentration of two to 10 per cent in lotions, collodion and ointments as a keratolytic agent. A familiar example is the combination of salicylic acid with benzoic acid (Whitfield's ointment), often prescribed for epidermophytosis. A particularly beneficial powder for ringworm of the feet has been described by Prehn (1938) and consists of five parts of salicylic acid, two parts of menthol, eight parts of camphor, 50 parts of boric acid and 35 parts of starch. The acid is also employed as a *wart* and *corn* remover (10 to 20 per cent in collodion) and in chronic skin diseases such as eczema. It is sometimes prescribed in talc (two to four per cent) against hyperhidrosis. Salicylic acid should not be used as a food preservative.

Methyl salicylate is reserved for external use as a counterirritant. It is employed for painful muscles or joints and can be diluted with two parts of olive oil or incorporated in an ointment. Some cutaneous absorption may occur but any benefit is due entirely to the local actions. Methyl salicylate is also used as a flavoring agent.

Phenyl salicylate is used only as an enteric coating material for capsules or tablets, when one desires to protect drugs from gastric secretions. The encapsulated material is released in the duodenum where the salol is hydrolyzed.

Sodium salicylate may be used for sclerosing varicose veins. Three to five cc of a 20 to 40 per cent sterile solution are injected.

Systemic Uses. *Antipyresis.* Antipyretic therapy is not as common today as it was formerly, and is reserved for those conditions in which fever in itself may be deleterious, or when the patient experiences considerable relief when the temperature is lowered. The tendency is to use baths and alcohol sponges rather than drugs. Little is known about the relationship between fever and immune processes, and the former may at times be a protective physiological mechanism. Again, the course of the patient's illness may be obscured by the relief of symptoms and the reduction of fever consequent upon the use of salicylates.

The antipyretic dose of salicylates is from 0.3 to 1.0 gram given orally as tablets or capsules every three or four hours. Better effects are obtained in cyclic fevers and when the drug is given to coincide with the expected defervescence. The antipyretic action of the salicylates is nonspecific and does not influence the course of the disease.

Analgesia. The salicylates are valuable for the *nonspecific relief* of certain types of pain arising from muscles, joints, and integumental structures, as for example, migraine, arthritis, dysmenorrhea, neuralgias, myalgias, etc. For this purpose salicylates are prescribed in the doses and manner outlined for antipyresis. A combination of drugs selected from different chemical groups is often more effective than a single substance, and represents one of the few valid uses of drug combinations. Thus salicylates are often combined with a barbiturate or codeine, together with either a pyrazolon or paraminophenol derivative. The combination should be ordered by the physician and in such relative doses as he deems necessary for the particular patient and illness. The use of proprietary preparations can only be deplored.

Use of Salicylates in "Cold," and "Grippe." The salicylates do not influence the course of the common cold or upper respiratory infections, and lack specific action in these disorders. They may make the patient more comfortable by reducing the temperature and relieving headache and muscle aching. If the symptomatic improvement tempts the individual to be ambulatory during his infection, the drug has done more harm than good. The use of gargles containing acetylsalicylic acid has no benefit other than those obtainable from solutions of sodium chloride.

Use of Salicylates in Gout. The salicylates are capable of relieving the acute attacks of gout when given in fairly large and repeated doses. They are somewhat inferior to cinchophen, especially for the therapy of chronic gout and the prevention of acute exacerbations. The probable mechanism of action and the results obtained are more fully discussed in connection with cinchophen (page 237).

Use of Salicylates in Acute Rheumatic Fever. Either sodium salicylate or acetylsalicylic acid may be used. The amount prescribed is much larger than that employed for any other purpose. A dose of 1.0 to 1.3 grams is given hourly until symptoms of salicylism ensue or until the desired clinical effects are obtained. This usually requires eight to 10 doses—a total of eight to 13 grams or more of salicylate. Acetylsalicylic acid is effective in a somewhat lower total dosage than sodium salicylate. After early toxic effects develop, such as ringing in the ears and dizziness, medication is omitted for 12 hours, and is then resumed at the lower dose level of 1.0 gram every four or five hours during the day. This is continued until all signs of active infection have been absent for a week or 10 days.

As stated previously, the mechanism of action is unknown. It is difficult to accept the conclusion that relief is entirely due to analgesia and antipyresis. Morphine, for example, relieves pain but does not affect the inflammation of the joints.

Despite the fact that migrating polyarthritis responds in a remarkable manner, the course of the disease is not shortened and complications are unchanged by salicylates. Usually within 24 to 36 hours there is apparent improvement or complete relief of pain, swelling, immobility, local heat, and redness of the joints. The fever and pulse rate are lowered and the patient feels greatly benefited. Complete relief is obtained in over 80 per cent of acute cases and failure occurs in only one to two per cent of patients. These dramatic changes do not occur in arthritis of streptococcal, gonococcal, or other origin. Therefore, the failure to obtain relief in suspected rheumatic polyarthritis is fairly good presumptive evidence that the diagnosis is faulty. At least, when rapid and characteristic benefit occurs, the diagnosis of acute rheumatic fever is strengthened.

No further joint involvement occurs during salicylate therapy. Cessation of medication, however, may result in recrudescence of symptoms. The elevated white blood cell count is also reduced by salicylates, and if the leukocytes remain at a normal level when medication is stopped, this is strong evidence that the infection has disappeared.

The management of the patient does not change because of salicylate medication, and absolute rest in bed, maintenance of fluids and nutrition, and careful attention to the heart must not be neglected merely because the patient is symptomatically improved. Cardiac complications in particular should be watched for, because salicylates do not in any way prevent their occurrence.

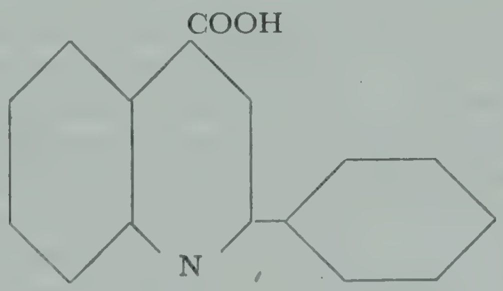
The many aspects of the therapy of rheumatic fever have been reviewed authoritatively by Cecil (1940).

Use of Salicylates in Ocular Inflammation. In cases of acute intra-ocular inflammation, the salicylates may give marked relief from pain and produce a diminution of inflammatory changes, such as congestion and swelling (Gifford, 1939). The mechanism of this action is unknown. Sodium salicylate or acetylsalicylic acid may be given in doses as large as those employed in acute rheumatic fever.

CINCHOPHEN

Cinchophen was synthesized in 1887 by Doebner and Gieseke, and was introduced into medicine under the trade name of *Atophan* by Nicolaier and Dohrn in 1908. As the term atophan suggests, the drug was proposed for the treatment of gout, and this still remains its chief use.

Chemistry and Preparations. Cinchophen is 2-phenylquinoline-4-carboxylic acid and has the following structural formula:



Cinchophen

Cinchophen is a yellowish-white bitter powder which is insoluble in water. It is official in the N.F. and in the B.P.

Pharmacological Actions. In nearly all its major actions, cinchophen resembles the salicylates. Its *antipyretic* and *analgesic* actions are similar to those of salicyl compounds, both in degree and mechanism. The *uricosuric* effect of cinchophen has already been discussed at length (page 227) and is more pronounced and more rapid than that of salicylates. A single dose exerts its greatest influence within three hours and is practically without further effect after nine hours. The ability of cinchophen to increase bile flow is said to be more pronounced than that of the salicylates. The *renal effects* are the same as for the salicyl drugs. The *antirheumatic* action of cinchophen has permitted its successful use in acute rheumatic fever.

Absorption, Fate and Excretion. Cinchophen is absorbed adequately from the intestinal tract. After cinchophen medication, the urine may assume a reddish color and turn green on the addition of acid, due to the presence in the urine of oxidation products, the exact chemical nature of which is disputed. Quantitative data on the excretion of cinchophen are lacking.

Doses and Administration. Cinchophen is always given orally, usually in capsules or tablets. The average analgesic or antipyretic dose is the same as that of sodium salicylate, namely, 0.3 to 1.0 gram every three or four hours. In rheumatic fever, the doses and intervals are the same as for the salicylates. The usual amount in acute gout is 0.5 gram every two hours for six or more doses.

Cinchophen, partly due to its acidity, causes a sensation of burning in the throat and irritation of the stomach. Experimentally, cinchophen has been employed in animals to produce gastric ulcers, and peptic ulcer has been recorded in human beings from the use of cinchophen (Block and Rosenberg, 1934; MacBryde, 1940). The gastric distress can be ameliorated by giving sodium bicarbonate, but the alkali is not to be mixed with the cinchophen. An ample amount of water should also be taken. When cinchophen is employed in patients with gout or with a tendency to form urate calculi, the combined use of water and sodium bicarbonate will prevent the precipitation of urate which is prone to occur in concentrated acid urines. Enough bicarbonate should be prescribed to make the urine alkaline, usually 15 grams on the first day of cinchophen medication when uric acid excretion is highest, and five to 10 grams on subsequent days. Potassium or sodium acetate or citrate may be used instead of sodium bicarbonate, but these do not ameliorate gastric irritation.

Toxicology. Before 1925, cinchophen was looked upon as a drug with approximately the same potentialities for poisoning as the salicylates. It causes all the symptoms of salicylism and produces skin lesions, angioneurotic edema and other allergic reactions similar to those from acetylsalicylic acid. Salicylism, however, does not occur quite so readily. In addition, cinchophen given to patients with cystitis may cause hematuria and pain in the bladder. Rarely, peptic ulcer may occur from the drug. The symptoms and treatment of acute poisoning by salicylates apply in all particulars to cinchophen.

Since 1925 an increasing number of cases of severe toxic reactions and fatalities from cinchophen have been reported. All of these have been due to a hepatotoxic effect of the drug. Up to 1936, 191 cases had been reported and 47 per cent were fatal. Other fatalities were reported subsequently (*see* Sugg, 1938; MacBryde, 1940). Probably hundreds of similar cases were unrecognized or unreported. It is true that the annual consumption of cinchophen in the United States alone was estimated at one time to be 90,000 pounds (White, 1931) and therefore the absolute incidence of liver damage is extremely low. Nevertheless, the serious nature of the lesion and the high mortality rate make it necessary that the physician give careful thought before using this drug. If cinchophen were an indispensable agent like morphine, there would be little question that its employment should continue despite the occasional untoward reaction.

The symptoms of liver involvement are much like those noted in delayed chloroform poisoning. Indeed, the initial symptoms may not be evident until the drug has been discontinued for days or weeks. Anorexia, nausea and vomiting are first noted and are soon followed by pruritus, icterus, fever, and hepatic tenderness and swelling. Stupor gradually develops and death may ensue after a few days or in a week or two. The capriciousness and unpredictability of cinchophen hepatitis are the most disturbing features about the drug. Toxicity is unrelated to dosage or to previous medication. The fact that a patient has taken cinchophen previously without ill effects is no guaranty that the next course of cinchophen will not cause jaundice and death. Large amounts may be taken for years without liver damage, and yet in other patients small amounts given for a few doses may prove fatal. Once symptoms have appeared, poisoning progresses despite discontinuance of medication. For this reason, Palmer and Woodall (1936) in their review of cinchophen poisoning conclude that "there is no safe way for the administration of cinchophen."

The nature of the liver injury is a toxic cirrhosis which may proceed to a fulminating yellow atrophy. The results of extensive animal experimentation have not elucidated the mechanism of this hepatotoxic action nor are they in accord with clinical experience. In man there appears to be a large and essential element of hypersusceptibility or idiosyncrasy which is not related to age, sex, allergy or previous use of the drug. It is possible that preexisting and clinically unrecognized liver damage may predispose to toxic reactions to cinchophen (Rawls and coworkers, 1939).

Inasmuch as the sensitivity of patients cannot be determined beforehand by any known test, the responsibility for the use of this drug rests upon the physician who elects to prescribe it. A major danger also exists in the lay use of proprietary drugs because more than 30 preparations have been placed on the market which are known to have contained cinchophen or its derivatives. In addition, at least 500 patented remedies have been advertised for the cure of rheumatic or uric acid disturbances, and probably a number of these included cinchophen (Hench, 1932). The present Federal control of the sale and distribution of cinchophen is to be commended.

The *treatment* of toxic cirrhosis due to cinchophen is symptomatic and supportive, and similar to that for chloroform and carbon tetrachloride injury to the liver. Surgical measures in patients with cinchophen hepatitis should be strictly avoided because the outcome is nearly always fatal. Intravenous administration of saline and glucose solutions is an important means of replacing the fluid and electrolyte lost incident to vomiting and diarrhea, and of giving nourishment, preventing acidosis and aiding the liver through replenishment of its glycogen stores. The diet should be high in carbohydrates and calcium and low in fats.

Therapeutic Uses. Cinchophen has no local uses analogous to those of the salicylates. The drug is employed for its systemic effects in the same manner and for the same conditions as are the salicylate compounds. Thus it is given for *analgesia* and *antipyresis,* but the possibility of toxic cirrhosis should certainly favor the selection of other agents for these purposes. Cinchophen is also effective in *acute rheumatic fever* where it compares favorably with the salicylates. Again, however, the choice of medication should be the salicylate drugs because they do not cause fatalities from liver injury.

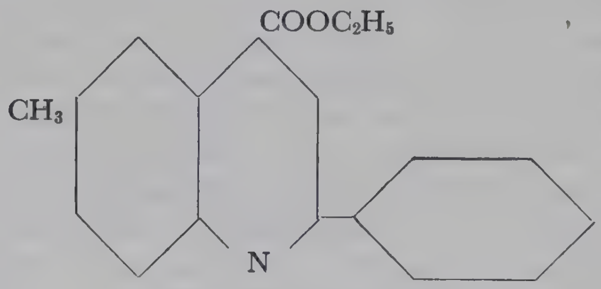
The disease for which cinchophen has been retained by some physicians, despite its known propensity as a hepatotoxic agent, is *gout.* Even here, however, there is no unanimity of opinion. Some clinicians, who treat many cases, claim to obtain satisfactory results from salicylates or colchicine, and therefore no longer use cinchophen. Others believe that in *chronic gout,* at least, there is no drug that can equal cinchophen for controlling the disease and preventing its progress to gouty nephritis and cerebral vascular or coronary complications. These complications may cause the death of the patient with chronic gout five years before his time, statistically speaking. Those who still use cinchophen believe the danger of the disease is greater than that of the drug (Hench, 1937). If cinchophen is employed for chronic gout, it may be given in the dose of 0.5 to 1.5 grams three times daily for three consecutive days each week. This is continued for months or even years. The drug should be given only under close medical supervision, and should be discontinued at the first sign of intoxication. As stated previously, this does not insure against serious or fatal poisoning. In the *acute attack of gout,* cinchophen gives no better results than can be obtained with salicylates or colchicine, and the latter drugs should be employed. If cinchophen is used, the dose is 0.5 gram every two or three hours for five or six doses.

In gout, the concentration of uric acid is high in the blood and low in the urine. The relation of gout to a faulty uric acid metabolism is generally agreed upon. The details of this association are so poorly understood, however, that the etiotropic effects of uricosuric drugs cannot be taken for granted. At least some of the relief obtained is on an analgesic and not on a specific basis. It is doubtful whether cinchophen actually decreases the urate deposit in tophaceous lesions or hastens their resolution. Cinchophen may give relief without noticeably affecting uric acid metabolism, and may fail to afford respite from an acute attack despite an increased uric acid output. Colchicine, as will be noted later, is quite effective without altering the uric acid content of the urine or blood.

Other measures employed in the acute attack of gout are morphine at the height of the pain, abundant fluids, purine-free diet, and local protection of the involved joint by cotton swathing.

NEOCINCHOPHEN

Neocinchophen, U.S.P., (novatophan, tolysin) is the ethyl ester of 6-methyl-2-phenylquinoline-4-carboxylic acid. Its structural formula is as follows:



Neocinchophen

It is a light yellow crystalline powder which is tasteless, odorless and nearly insoluble in water.

Actions and Uses. In all its pharmacological actions, neocinchophen resembles cinchophen. It has the advantage of being almost non-irritating. Intestinal absorption, however, may be incomplete as a result of its limited solubility. It is apparently absorbed as such, and is excreted in the urine partly unchanged and partly as an oxidation product.

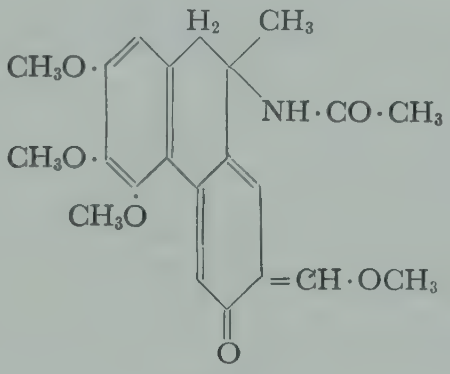
The clinical uses and dosages of neocinchophen do not differ from those of cinchophen itself. The question arises whether neocinchophen is as toxic as the parent compound. Experimental data on animals seem to indicate a higher margin of safety which appears to be due to the rather poor intestinal absorption of neocinchophen. Symptoms of salicylism do not occur as often as with cinchophen.

In man, the incidence of toxic cirrhosis of the liver following neocinchophen medication is difficult to determine because of inaccurate data on the extent to which this drug is used. An analysis of the seven cases of serious neocinchophen poisoning reported in the literature up to the middle of 1936 showed that five deaths occurred (Palmer and Woodall, 1936). The alleged greater safety of neocinchophen is still a moot point, and the burden of proof rests on those who make this claim.

COLCHICUM

Colchicum autumnale is the autumn crocus (meadow saffron) whose seeds and corm contain an alkaloid, *colchicine,* which is effective in the treatment of acute attacks of gout. It has no other therapeutic uses, although it is valuable experimentally for its effects on plant and animal cell division. The poisonous action of colchicum was known to Dioscorides but its use in gout dates from the sixteenth century.

Chemistry and Preparations. The structural formula of colchicine is as follows:



Colchicine

Colchicum seeds, the U.S.P. source of colchicine, contain about 0.5 per cent of the alkaloid. The preparations and doses used are *Colchicine,* U.S.P., 0.5 to 1.0 mgm; *Tincture of Colchicum Seed,* U.S.P., 1.0 to 2.0 cc (*Tincture of Colchicum,* B.P., 0.3 to 1.0 cc); *Strong Tincture of Colchicum Corm* (Wine of Colchicum Corm), N.F., 0.6 cc; *Dry Extract of Colchicum,* B.P., 0.015 to 0.060 gram; *Liquid Extract of Colchicum,* B.P., 0.12 to 0.3 cc.

Pharmacological Actions. *Gout.* Colchicum occasionally affords dramatic relief in acute gout. The drug has no effect on uric acid metabolism. It does not relieve other types of pain or inflammation and the mechanism of relief in gout is inexplicable.

White Blood Cells. In several species of animals, colchicine produces a temporary leukopenia which is soon replaced by a more lasting leukocytosis. This is sometimes due to a striking increase in the number of basophilic granulocytes. The site of action is apparently directly on the bone marrow.

Mitotic Arrest of Rapidly Dividing Cells. Colchicine, in proper concentrations, has the ability to arrest cell division in the metaphase and to cause bizarre mitotic figures (Dustin, 1934; Brues and Jackson, 1937). Larger doses may completely prevent cells from entering mitosis. This remarkable action of the drug holds *in vitro* and *in vivo* for normal cells, rapidly regenerating cells and for cancer cells, and has been employed to study the rate and characteristics of abnormal cell growth (Oughterson and coworkers, 1937), as well as the effects of carcinogenic agents and endocrine substances on these properties (Allen and coworkers, 1937). It has also been used to produce regression in certain types of experimental tumors. A number of colchicine derivatives have been found to act in a similar manner (Brues and Cohen, 1936), but the exact chemical grouping necessary for this property remains undetermined. The failure of the mitotic spindle to develop and function normally is thought to be the cause of the arrest of cell division (Ludford, 1936). That colchicine is not specific is indicated by the fact that sodium cacodylate produces similar nuclear abnormalities (Dustin, 1934).

Toxicity. Colchicine poisoning usually results from clinical overdosage. At one time colchicum was employed for criminal poisoning. An interesting but unexplained feature of the intoxication is the latent period of several hours or more between the administration of the drug and the onset of symptoms. This interval is not altered by dosage or route of administration. Evidence has been produced that colchicine must first be changed to a toxic oxidation product (oxydicolchicine).

Gastro-intestinal symptoms are the first to appear, probably as a result of the excretion of the drug by this channel. There is severe abdominal pain, nausea, vomiting and diarrhea. The diarrhea soon becomes profuse, watery and bloody due to a hemorrhagic gastro-enteritis. Considerable fluid, electrolyte and blood plasma are lost through the bowel, and in this respect the picture is similar to that of acute arsenic poisoning. Even when given by injection, colchicine causes gastro-intestinal irritation and burning of the throat and skin. Because of the extensive vascular damage, the shock syndrome occurs.

The kidney, another site of excretion of colchicine, is also injured and hematuria and oliguria follow. The pulse is rapid and weak and the patient greatly exhausted. Muscular depression is pronounced, an ascending paralysis of the nervous system develops, and death results from respiratory arrest usually within a day or two. Consciousness is present to the end, but terminal delirium or convulsions may appear.

Fatal Dose. This varies considerably. Fifteen cc of the tincture of colchicum seed, corresponding to six mgm of colchicine, have proved fatal but the patient may survive larger doses.

Treatment. In addition to gastric lavage, therapy should be directed very early against shock. The remaining measures are purely symptomatic and supportive. Atropine and morphine aid in relieving abdominal pain. Artificial respiration should be tried when paralysis begins to involve the cervical region of the spinal cord.

Clinical Uses. Colchicine is used in gout on an entirely empirical basis. Better results are obtained in the acute episodes and the drug should be used as early in the attack as possible. Many patients fail to respond to colchicine but some experience striking benefit. The pain, swelling and redness are relieved within a few hours and the attack is brought to an abrupt close. Some early gastro-intestinal side-actions, such as diarrhea, must be tolerated before the patient is benefited. Colchicine is practically valueless in chronic cases, and continued treatment with it does not appear to lessen the frequency of gouty episodes. Colchicine is usually given in tablet form in a dose of one mgm and repeated every two or three hours for four or five doses. If colchicine is available there is reason to prefer it because the wine and tincture are more uncertain in their effects, probably due to deterioration. Many patients experience gastric distress or diarrhea on the second day of treatment. If severe nausea, diarrhea or great weakness is experienced, medication should be stopped and other measures used. Also, the drug should not be continued after the pain has been relieved.

CHAPTER 14

ANALGESICS AND ANTIPYRETICS

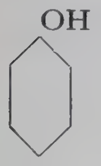
II. ACETANILID AND ACETOPHENETIDIN; AMINOPYRINE AND ANTIPYRINE

ACETANILID AND ACETOPHENETIDIN

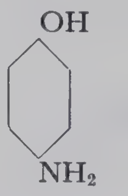
Acetanilid and acetophenetidin are known as "coal-tar" antipyretics. They are sometimes termed paraminophenol derivatives, although strictly speaking acetanilid cannot be classified in this way. These drugs are also called aniline derivatives, a designation too broad to be helpful. In the body, as will be noted later, it is likely that both acetophenetidin and acetanilid exert their typical action after being changed to paraminophenol.

Acetanilid was introduced into medicine as an antipyretic under the name of *antifebrine* by Cahn and Hepp in 1886. The early reports of serious poisoning from the drug prompted the search for less toxic compounds. *Paraminophenol* itself was tried in the belief that the body oxidized acetanilid to this compound. Toxicity was not lessened, however, and a number of chemical derivatives of paraminophenol were then tested. The most satisfactory of these was *acetophenetidin,* introduced under the trade name of *"phenacetine."* This compound and acetanilid are the only two which have survived the past 50 years of clinical trial, but the less toxic salicylates have overshadowed the use of these drugs both as analgesics and antipyretics. Acetanilid and acetophenetidin are common constituents of headache and "pain-killing" mixtures of secret composition, and most poisonings by this group of drugs result from the lay use of such patent medicines.

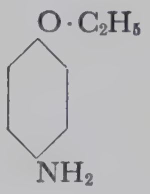
Chemistry and Relation of Chemical Structure to Action. The relationship between phenol, aniline and the drugs under discussion can be seen by an inspection of their structural formulas.



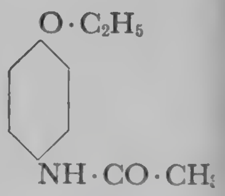
Phenol



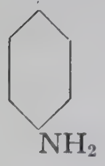
Paraminophenol



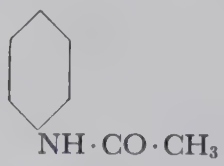
Phenetidin



Acetophenetidin



Aniline



Acetanilid

The *antipyretic action* of these compounds resides in the aniline structure, and aniline itself is antipyretic but its toxicity precludes its clinical use. Introduction of other radicals into the OH of paraminophenol and into the free amino group of aniline reduces toxicity without loss of antipyretic action. Best results are obtained when an alkyl group is substituted in the OH (ethyl in acetophenetidin) and an acid group in the NH_2 of aniline (acetyl in acetanilid and acetophenetidin).

It is believed that both acetanilid and acetophenetidin owe their therapeutic as well as their toxic actions to conversion in the body to paraminophenol. In the case of acetanilid, this requires the addition of an hydroxy group in the position para to the amino group. That this may occur in the body is suggested by the *in vitro* work of Michel, Bernheim and Bernheim (1937) whose study indicates that acetanilid is hydrolyzed by various tissues to acetic acid and aniline, and that aniline in the presence of tissue may be oxidized to p-aminophenol.

Pharmacological Actions. The two chief systemic actions of acetanilid and acetophenetidin are *antipyresis* and *analgesia.*

Antipyresis. This action does not differ from that described for the salicylates. Acetanilid and acetophenetidin act on the heat-regulating centers of the nervous system to bring about a greater dissipation of body heat through cutaneous vasodilatation. A measure of *tolerance* is said to develop to the antipyretic action in some patients.

Analgesia. The mechanism of obtundation of pain by acetanilid and acetophenetidin is similar to that described for the salicylates. The action is central, probably on the optic thalamus. The type of pain relieved is that which usually occurs in headache, and in many muscle, joint and peripheral nerve affections. Intense pain or that arising from smooth muscle spasm in hollow viscera is not alleviated. The nature of this limited analgesic action is not understood, but it is selective and the drugs are not central depressants as are the hypnotics. Acetophenetidin may raise somewhat the cutaneous threshold for touch, but this modality of sensation is not affected nearly to the same extent as is pain.

Absorption, Fate and Excretion. Acetanilid and acetophenetidin are quickly absorbed from the gastro-intestinal tract. In the body they are probably converted to paraminophenol and possibly to hydroxyphenylhydroxylamine. They are excreted rapidly by the kidney as conjugation products with glycuronic and sulfuric acids and can impart a dark amber or wine color to the urine, which may turn dark brown or black especially if it has been exposed for some time to the air. The urine may give a positive "indophenol" test as a result of the conjugated excretory substances.

Doses and Preparations. *Acetanilid,* U.S.P., and *Acetophenetidin,* U.S.P., B.P. (phenacetin), are white crystalline powders. They are always given orally, usually in powder, capsule or tablet form, being too insoluble to be prescribed in aqueous solution. If they are used in powder form, their taste is not objectionable. The average single dose of acetanilid for adults is 0.2 gram, and that of acetophenetidin 0.3 gram. If given in mixtures, the drugs should not be prescribed with antipyrine because liquefaction occurs.

Therapeutic Uses. The analgesic and antipyretic uses of these compounds are exactly the same as for the salicylates. In contrast to the salicylates, however, acetanilid and acetophenetidin are not employed for relief in gout or rheumatic fever because they lack an uricosuric action or any "specific" effect on the polyarthritis of acute rheumatic fever. In addition, they are considerably more toxic than the salicylates and cannot be used as continuously or in such large doses without risk of poisoning.

Analgesic Uses. In headache, migraine, dysmenorrhea, arthralgia, myalgia and similar disorders, a therapeutic dose of acetanilid or acetophenetidin may be given every three or four hours. Medication over a period of days is not advised unless there are intermittent periods during which analgesic drugs from other chemical groups are substituted. If ordinary doses are ineffective, larger amounts as a rule do not give relief.

As emphasized for the barbiturates and again for salicylates, a smoother and more efficient analgesic action may be obtained by prescribing a mixture of two or three analgesic chemicals. These should be selected from different classes of drugs and the dose of each reduced to one-half or less. This represents one of the few valid uses of drug combinations. The possibility of untoward reactions is also reduced because the toxic effects of the salicylates, pyrazolon and paraminophenol derivatives differ somewhat from each other. Often a barbiturate or codeine may be added to such a mixture, and caffeine is a frequent constituent of analgesic combinations prescribed for headache.

There is probably no other field in which commercial drug exploitation is so extensive as in the manufacture and over-the-counter sale of *headache nostrums.* Many of these preparations contain acetanilid, acetophenetidin and amidopyrine, all of which are capable of causing serious and even fatal intoxication. Salicylates are also commonly included. The names of these "patent" medicines usually give no indication as to the nature of their drug content. Their wide use by the laity cannot be too forcefully deplored and condemned.

Antipyretic Uses. The original use of acetanilid and acetophenetidin to reduce fever has been supplanted by their employment for relief of pain. The antipyretic dose has been stated previously. The indications and rationale for reducing body temperature are discussed in connection with the salicylates, and apply to these drugs also. It is perhaps best to give smaller doses at intervals of one or two hours than to prescribe the full dose every three or four hours.

Toxicology. Poisoning by acetanilid and acetophenetidin nearly always occurs from their medicinal misuse rather than from attempts at self-destruction. Most cases of intoxication have resulted from the ingestion of proprietary drug mixtures, usually headache powders. Poisoning may be acute or chronic, but the latter is the more frequent type and death may result from either. Acetanilid is definitely more toxic than acetophenetidin, perhaps because the latter is less soluble and is oxidized very slowly in the body to more toxic products. Considerable individual susceptibility is manifested to these drugs and the toxic dose for one patient may be harmless for another. The cause of this variation is unknown. Undoubtedly the nature of the disease for which the drugs are taken can add greatly to the untoward reactions caused by them. Most of the early reports of death from acetanilid were definitely due to overdosage because the potentialities for poisoning from the chemical were not at first appreciated.

Acute Poisoning. Symptoms. The most outstanding characteristic of acetanilid poisoning is *cyanosis.* Acetophenetidin causes this symptom much less frequently. The cyanosis is due to alterations of hemoglobin to *methemoglobin* and *sulfhemoglobin.* Many of the signs and symptoms of intoxication are a direct result of this change in blood pigment. The patient shows a bluish color of the skin, mucosa and finger nails and the altered pigment may be detectable on spectroscopic examination of the blood. This diagnostic test is not always positive because a higher concentration of methemoglobin is needed for detection by the usual laboratory spectroscope than is necessary to produce cyanosis and clinical symptoms. Therefore, the absence of the characteristic absorption bands for methemoglobin, upon examination of the blood of a patient suspected of acetanilid or acetophenetidin poisoning, does not necessarily exclude these chemicals as the cause. In severe cases of poisoning, the blood is often chocolate-colored due to its high content of methemoglobin.

The conversion of hemoglobin to methomoglobin and sulfhemoglobin occurs within the red blood cells and the latter are not injured as a rule. High concentrations of the drug, however, may occasionally result in actual destruction of the corpuscles. This is especially true for the related chemicals—aniline, nitrobenzene and phenylhydrazine. Acute intravascular hemolysis of a large number of red blood cells is a serious complication. The ensuing anemia may be profound and the red cell count may fall quickly to levels between one to two million per cubic mm. In addition to symptoms of anemia, renal function is seriously impaired and the urine contains albumin, casts, red blood cells and free methemoglobin. Oliguria or anuria may occur as it also does in cases of hemoglobinuria resulting from faulty blood transfusions. The blood contains free methemoglobin and cell membrane fragments. There is also leukocytosis and the blood smear in some respects is similar to that seen in the acute episodes of hemolytic jaundice or sickle cell anemia.

The mechanism of formation of methemoglobin and sulfhemoglobin by acetanilid and acetophenetidin is a matter of dispute. These drugs do not form the pigment when added to blood in a test tube. In the body, however, some change occurs which makes them capable of reacting with hemoglobin. Paraminophenol, for example, will promote methemoglobin formation *in vitro*. It is possible that paraminophenol or some oxidation product such as hydroxyphenylhydroxylamine is the substance responsible for the alteration in hemoglobin (Brownlee, 1939). There is also the possibility that some highly pigmented oxidation product of paraminophenol may be present in the blood and tissues and in itself cause or enhance the bluish color of the skin. Residual discoloration of both the blood and skin exists for some time after sulfhemoglobin and methemoglobin have disappeared and suggests such an explanation.

Methemoglobin is incapable of acting as a respiratory pigment. The reduction in the amount of hemoglobin available for oxygen transport results in *functional anemia*. Symptoms such as dyspnea, vertigo, weakness and anginal pain are prominent. In more severe cases, circulatory failure may ensue, the temperature is subnormal, prostration is marked, and respiration is rapid and shallow. The blood pressure is low and the pulse is rapid, weak and irregular. *Vascular collapse* is due not only to the relative anoxemia but also to a direct depressant action of high concentrations of acetanilid or acetophenetidin on the heart and blood vessels. Vascular dilatation and injury occur and set the stage for the *shock syndrome*.

Parenchymatous organs are also damaged, especially the liver, and the patient may develop jaundice. The *skin reactions* to toxic doses of these drugs may be a prominent feature and are noted especially with acetophenetidin. They are usually erythematous or urticarial in nature, but may be more serious and accompanied by mucosal lesions of the mouth. *Fever* may accompany the drug rash. Symptoms of *cinchonism* may occur but this is quite uncommon.

In the more severe grades of intoxication, *central nervous system stimulation*, excitement and delirium may be noted. This is followed by depression and stupor. Terminal asphyxial convulsions may develop. Death is usually preceded by a period of *collapse* and *coma*, and occurs suddenly or may be delayed for several days

The toxicity of acetanilid for the *heart* has received considerable attention. Ordinary therapeutic doses are not injurious to the normal heart but individuals with organic disease of cardiac or pulmonary origin are naturally more susceptible to the cardiovascular effects of the drug. Also, patients with anemia are more likely to develop symptoms of poisoning from the immoderate use of acetanilid or acetophenetidin. Indeed, in anemic individuals, the cyanosis may not be apparent despite a dangerously high concentration of methemoglobin. The repeated administration of these drugs to patients with anemia, or cardiac, pulmonary, renal or hepatic disease is definitely contraindicated.

The *fatal dose* of acetanilid cannot be stated accurately. As much as 4.0 to 8.0 grams has been taken without fatal results although smaller doses are claimed to have caused death. Animals survive proportionately much larger doses (Smith, 1940), and it is not clear whether a number of the reported human deaths attributed to the drug may not have been due in large part to underlying disease.

Chronic Poisoning. This may be extremely difficult to diagnose. Some chronically poisoned patients continue to take the drug for relief of the very symptoms caused by it. The cyanosis frequently present is often mistaken for a sign of congenital heart lesions or pulmonary disease. In addition to the suggestive skin and mucosal color, the patients complain of shortness of breath and severe weakness. There are also loss of weight, anorexia, digestive disturbances, and insomnia. Anemia is often prominent, and though it usually has the characteristics of the secondary type the blood occasionally may show elevated color and volume indices similar to those of primary anemias or acute hemolytic dyscrasias. There may also be a leukocytosis. Disturbances in the blood clotting mechanism may occur and metrorrhagia may be a presenting symptom of chronic acetanilid poisoning in women. The urine is sometimes brownish in color and gives the positive indophenol test. Rarely the blood may show methemoglobin or sulfhemoglobin, and its oxygen carrying capacity is then lower than is indicated by the hemoglobin content. This finding is of diagnostic importance, but many clinical laboratories are not equipped to do blood gas analyses. Of course, the diagnosis can be confirmed only by the patient's admission that the offending drug was ingested. This requires painstaking, diligent and often repeated questioning, and necessitates a knowledge of the names of the many proprietary nostrums which contain acetanilid or acetophenetidin.

Treatment. There is no specific therapy for *acute poisoning* by these drugs. If they have been recently ingested, gastric lavage should be performed and a solution of magnesium sulfate administered before the tube is withdrawn. Transfusion of blood may be needed to relieve the cyanosis and functional anemia in severe cases of intoxication. Artificial respiration may be required. Inhalation of oxygen and carbon dioxide is helpful. If an acute, severe hemolytic anemia occurs, blood transfusion is definitely indicated. This procedure also aids in protecting the kidneys against damage from the intravascular hemolysis. Sufficient alkali may also be given to make the urine alkaline in an attempt to prevent the further precipitation of free hemoglobin in the renal tubules with resulting obstruction to the flow of urine. Alkalis may also aid the reconversion of methemoglobin to ordinary oxyhemoglobin, as also does the administration of low doses of methylene blue (page 1032). The development of the shock syndrome calls for the measures outlined elsewhere.

In chronic poisoning, the drug must be completely withdrawn and supportive measures adopted to assist the patient back to health. These include the use of iron salts for the anemia. The blue color may not fade completely until several weeks after the cessation of the drug. The patient should be warned against the offending medicine. Rarely, a person may become habituated to acetanilid and continue to take it for a number of years. It has been reported that withdrawal symptoms of restlessness and excitement may appear for three or four days when medication is stopped (Payne, 1935), but it is extremely doubtful that true addiction occurs. The habit-forming properties of the analgesic-antipyretic drugs, however, cannot be denied.

ANILINE

Aniline, $C_6H_5NH_2$, is aminobenzene. It is purely of toxicological importance and has no medicinal uses. Aniline is a colorless oily liquid with a characteristic odor. Only after exposure to air does it acquire the brownish discoloration so often associated with it. Aniline produces the same general pharmacological effects as acetanilid but causes serious poisoning in amounts as small as 0.1 to 0.25 gram. It is of interest first because it provides the starting point for the manufacture of a number of drugs, and secondly because its wide use in industry ranks it as an important industrial hazard. Among other things, it is used in the synthesis of the aniline dyes, and in the manufacture of rubber and photographic materials. Poisoning is usually complicated by the fact that the aniline used industrially is impure and contains other toxic substances such as xylidine and toluidines. Intoxication may occur from inhalation of aniline vapors, from swallowing the chemical or from cutaneous absorption. The liquid can readily be absorbed through the intact skin and serious reactions have occurred from wearing apparel such as shoes newly dyed with chemicals containing aniline.

Symptoms of Acute Aniline Poisoning. The outstanding feature of aniline poisoning is methemoglobinemia. In the body, aniline is changed to the same intermediate oxidation products, paraminophenol and hydroxyphenylhydroxylamine, as is acetanilid and these are probably the cause of the methemoglobin formation. Cyanosis is so prominent a sign that workmen call aniline poisoning (and closely related nitrobenzene intoxication) the "blues." The symptoms and signs are essentially those described in detail for acetanilid. There is vertigo, headache, mental confusion, weakness and a desire to sleep. The skin and mucosa are blue and the pulse is fast and weak. The methemoglobinemia is more pronounced than in acetanilid intoxication and therefore poisoning is much more severe. The red blood cells are more apt to undergo intravascular hemolysis, with the resultant deleterious renal effects. The functional anemia due to methemoglobin is thus complicated by actual anemia.

Effects on the central nervous system are more prominent than in acetanilid poisoning and in the preliminary excitement stage the patient may appear to be inebriated. Later, there may be delirium followed by stupor and coma. Aniline is more toxic to the heart than is acetanilid, and cardiac collapse is more frequent. The action on the blood vessels is also more marked, and shock therefore is often present. If the patient survives sufficiently long, jaundice develops and blood cells and hematoporphyrin may appear in the urine. The liver and kidneys are likewise more severely damaged by aniline than by acetanilid. Death usually occurs within the first 24 hours from heart failure rather than from respiratory paralysis.

The *fatal dose* of aniline for human beings is difficult to state. Recovery has followed the swallowing of 75 cc, and death has resulted from one-third this amount. Again, as was stated, 0.25 cc may cause alarming symptoms.

Treatment. If aniline vapors have been inhaled, the victim should be removed immediately to the fresh air. Gastric lavage should be performed without delay if aniline was swallowed. When aniline has been spilled on the skin, it should be washed off promptly with copious amounts of water; but, if available, ether or alcohol is preferable to water because aniline is very soluble in these reagents. Treatment is the same as that outlined for acetanilid, with special emphasis on shock therapy, support to the cardiovascular system, and correction of the acute anemia with blood transfusion if necessary.

Chronic Aniline Poisoning. This occurs from repeated exposure to aniline in industry. Anemia is often marked and the usual train of symptoms from it are prominent. There is loss of appetite and weight, and cutaneous lesions are commonly noted. These are eczematoid in character and may become secondarily infected due to the poor health of the patient. Bladder symptoms are noted and consist of painful urination, frequency and urgency. The urine may be colored a dark brown due to the presence of conjugation products of paraminophenol. A high incidence of papilloma of the bladder occurs in workers in aniline industries, and this fact has been the subject of considerable investigation. These tumors apparently also occur from nitrobenzene and are thought by some to be due to oxidation products excreted in the urine which are irritant to the bladder even in high dilution. *Treatment* is purely symptomatic and removal of the patient from contact with the offending chemical is essential. Recovery may be slow. The bladder tumors may prove fatal.

NITROBENZENE

This chemical, $C_6H_5NO_2$, is a yellow, oily fluid which has the odor of oil of bitter almonds—benzaldehyde. It is important purely from a toxicological standpoint and has no uses in medicine. Aniline is obtained chemically from the reduction of nitrobenzene and the two chemicals are used similarly in many industrial processes. In addition, nitrobenzene, because of its pleasant odor, is employed as an artificial flavoring agent in foods, perfumes, soaps, etc. It is quite volatile and the vapors are more toxic than the liquid itself.

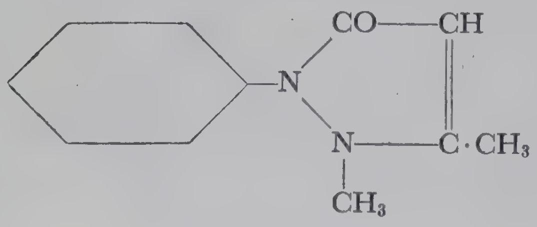
Poisoning. Nitrobenzene resembles aniline in being highly toxic to the blood and heart, but in addition it is a strong central nervous system depressant. Stimulation, however, may precede this depression. When nitrobenzene is swallowed, symptoms are often delayed for several hours. They then appear rather suddenly and in severe form. Inhalation of the vapors, on the other hand, promptly gives rise to marked effects. In either case, the patient acts as if he were inebriated. Headache, dizziness, nausea and vomiting, depressed respiration and visual disturbances are noted, and stupor and coma then follow. Death results from respiratory arrest. The blood changes are like those produced by aniline and the cyanosis is intense. It is claimed that both methemoglobin and nitrobenzene-hemoglobin are present. The blood is chocolate colored and acute hemolysis of red blood cells is not infrequent. The dark urine has the diagnostic odor of oil of bitter almonds, and this feature also characterizes the vomitus. *Treatment* is the same as for aniline poisoning.

Chronic intoxication results from repeated industrial exposure to nitrobenzene. It is characterized by cyanosis, visual disturbances, anemia, cachexia, peripheral neuritis and dysuria due to bladder irritation. Benign and malignant bladder papillomata apparently occur as in chronic aniline poisoning. *Treatment* is purely symptomatic and resembles that for chronic aniline poisoning.

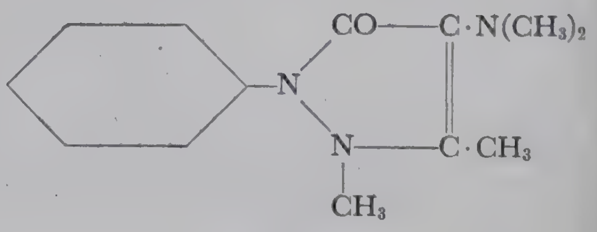
AMINOPYRINE AND ANTIPYRINE (PYRAZOLON DERIVATIVES)

Antipyrine (phenazone) was introduced into medicine in 1884. A few years later, a closely related compound, *aminopyrine* (amidopyrine), was synthesized and used clinically. Both antipyrine and aminopyrine were originally employed for antipyresis, but are now more often prescribed for analgesia. They share the general pharmacological properties of the salicylates and the paraminophenol derivatives, but differ somewhat in the type of poisoning they produce. This is especially true of aminopyrine which can cause severe and often fatal agranulocytic angina. For this reason, the clinical use of aminopyrine has been sharply curtailed. Antipyrine lost favor as the salicylates became more prominent, and it is rather infrequently prescribed today.

Chemistry. Both antipyrine and aminopyrine are phenyl-pyrazolon derivatives, aminopyrine being the dimethyl amino derivative of antipyrine. Their structural formulas are as follows:



Antipyrine



Aminopyrine

Pharmacological Actions. The two main systemic actions of aminopyrine and antipyrine are *analgesia* and *antipyresis*. In this respect they resemble the salicylates, acetanilid and acetophenetidin. In addition, antipyrine has some mild local anesthetic and antiseptic properties. Neither antipyrine nor aminopyrine shares the uricosuric action of the salicylates and cinchophen, but aminopyrine has the same antirheumatic effects. It can therefore be used in acute rheumatic fever. Other actions of these drugs are reserved for discussion in the section on poisoning.

Local Actions of Antipyrine. Antipyrine shares the local antiseptic property of the salicylates but the action is too weak to be of medicinal value. This drug is also a mild local anesthetic and was formerly used for anesthesia of the mucous membranes of the throat.

Analgesia and Antipyresis. The mechanism of antipyresis and analgesia produced by antipyrine and aminopyrine is similar to that of the salicylates. In equivalent doses, aminopyrine is more effective than antipyrine. Traditionally, aminopyrine has been used for analgesia and antipyrine for reducing fever, but there is no sound reason for this distinction. The analgesia may be enhanced if a combination of several drugs from different chemical groups is prescribed, as suggested under the salicylates.

Doses and Preparations. *Aminopyrine* (Amidopyrine) and *Antipyrine* (Phenazone) are official in the U.S.P. and B.P. Both drugs are white crystalline, odorless powders. The average dose of either aminopyrine or antipyrine for adults is from 0.3 to 0.6 gram, and this may be repeated at intervals of four hours. Although both compounds are soluble in water (antipyrine, 1:1, aminopyrine, 1:18), they are nearly always given orally in tablet or capsule form. Antipyrine liquefies when combined with acetanilid or acetophenetidin. *Melubrin* (N.N.R.) is another pyrazolon derivative which has not gained wide favor in the United States. It is closely allied to antipyrine which it resembles in pharmacological properties and therapeutic uses.

Absorption, Fate and Excretion. Both drugs are absorbed rapidly from the intestinal tract. There is little information on the fate of aminopyrine but it is probably similar to that of antipyrine which may be excreted in the urine unchanged or as oxidation products in conjugation with sulfuric and glycuronic acids. The urine may become blood-red in color after antipyrine and appear green in reflected light, but this is seen only after large doses.

Therapeutic Uses. These drugs are employed for *analgesia* and *antipyresis* in a manner exactly similar to the use of salicylates and paraminophenol derivatives. The action of aminopyrine is slower in onset but more enduring than that of antipyrine. In *rheumatic fever*, aminopyrine has been found to be as effective as the salicylates or cinchophen. The dose is much smaller than for the salicylates. For the first day of medication, 0.3 gram of aminopyrine is given every four hours for five doses (1.5 gram total dose). On subsequent days this can be reduced to 1.0 gram or less per day. The drug does not cause gastric distress as do the salicylates, and thus will not confuse the interpretation of abdominal symptoms due to early cardiac failure or overdigitalization. Despite these advantages and regardless of the fact that no serious untoward reactions have been reported from the use of aminopyrine in rheumatic fever, this drug should not be employed because of the danger of agranulocytosis. This is especially true because the salicylates are effective in acute rheumatic fever.

Toxicology. Poisoning from antipyrine and aminopyrine resembles that from acetophenetidin and acetanilid with the important exception that methemoglobinemia and cyanosis seldom occur. Large doses of antipyrine may occasionally cause alterations of hemoglobin but aminopyrine apparently does not affect the red blood cells. The effects on the central nervous system are more prominent with aminopyrine. In animals, stimulation sufficient to cause convulsions is produced, but this is rarely seen in human poisoning. Skin eruptions are more prone to occur after antipyrine, small doses of which may cause in certain patients a skin reaction similar to that seen with phenolphthalein. This consists of macular patches which are round or oval and vary in size from a few millimeters to several centimeters. They are pink or dark purple in color, last for months after the drug has been stopped, fade slowly, and leave pigmented areas which may flare up if the medicine is again taken. Aminopyrine is more likely to cause herpes labialis and angioneurotic edema in sensitive patients. The further details of the symptoms of poisoning may be found under acetanilid. The *treatment* is the same as for poisoning by the latter drug. If convulsions occur which are not terminal or asphyxial in character, they may be controlled by injection of a soluble short-acting barbiturate.

Aminopyrine Agranulocytosis. There are a number of drugs which are capable of producing severe and often fatal agranulocytosis. Among these are the arsenobenzenes, gold salts, dinitrophenol, benzol and sulfanilamide. Aminopyrine, however, occupies a peculiar position in this group because all the other chemicals can also produce disturbances of the red blood cells or platelets. Thus sulfanilamide causes acute hemolytic anemia; gold produces thrombopenic purpura; and benzol, dinitrophenol and arsenobenzenes may produce aplastic anemia and thrombopenia (Witts, 1936; Kracke, 1938; Fitz-Hugh, 1938). Aminopyrine can cause true agranulocytic angina in the sense that there is a marked leukopenia with an almost total absence of granulocytes, a maturation arrest of granulocytes at the stem stage in the bone marrow and no alterations in red blood corpuscles or platelets. This is the only drug of the analgesic-antipyretic or sedative-hypnotic group which is definitely known to cause the agranulocytic syndrome. The white cell count may be as low as 100 cells per cubic mm, the cells consisting entirely of lymphocytes. Fever, malaise, and ulcerations of the throat and other mucous membranes are often prominent. This syndrome, now known as agranulocytic angina, was first described by Schultz in 1922.

When the reports of aminopyrine as a cause of granulocytopenia first appeared in the early 1930's, it was not entirely clear whether aminopyrine or other drugs used in combination with it, such as the barbiturates, were responsible for the disorder. This point has been definitely settled and there is now no doubt that aminopyrine is the causative agent. The barbiturates definitely do not cause agranulocytic angina.

The *evidence for the causative rôle of aminopyrine* in agranulocytic angina has not always been dependable. In some cases at least, there was reason to suppose that the patient may have had the early symptoms of the disease and then taken aminopyrine for relief. A sufficient number of reports are now available, however, clearly to implicate aminopyrine as the causative agent. Indeed, there are some workers who are inclined to believe that aminopyrine is the sole cause of the disease. In certain individuals who have recovered from an agranulocytic attack it is possible to demonstrate an extreme sensitivity to the drug, because the ingestion of a small amount of aminopyrine results in the return of the characteristic blood picture and symptoms (Figure 22).

That there must be some large and determining element of *individual* *hypersusceptibility* in aminopyrine agranulocytosis is indicated by the low incidence of this bone marrow dyscrasia in comparison with the wide use of the drug. On the other hand, it is true that many cases have not been reported or have been unrecognized. What determines this hypersusceptibility is unknown. It is unrelated to sex, dose or previous use of the drug. Skin tests of the scratch, intradermal, patch or passive transfer type have yielded negative results. Dameshek and Colmes (1936), however, have demonstrated that when the drug is first incubated with the blood serum of the patient and the mixture injected intradermally, positive skin reactions may be obtained and are often accompanied by all the clinical and hematological features of agranulocytic angina (Figure 105). This suggests that a linkage between serum and drug may be essential for aminopyrine sensitivity. This observation is supported by the work of Landsteiner and Van der Scheer (1933) who found that the new antigenic property of substances formed by proteins linked to single chemicals was related to the non-protein part of the combination in regard to specificity. A typical blood response obtained by Dameshek and Colmes is presented in Figure 22. This illustrates the comparable effects of a large oral dose (0.6 gram) and a minute intradermal dose (10 mgm) of aminopyrine in a sensitive individual, and also clearly shows that skin testing is not without danger.

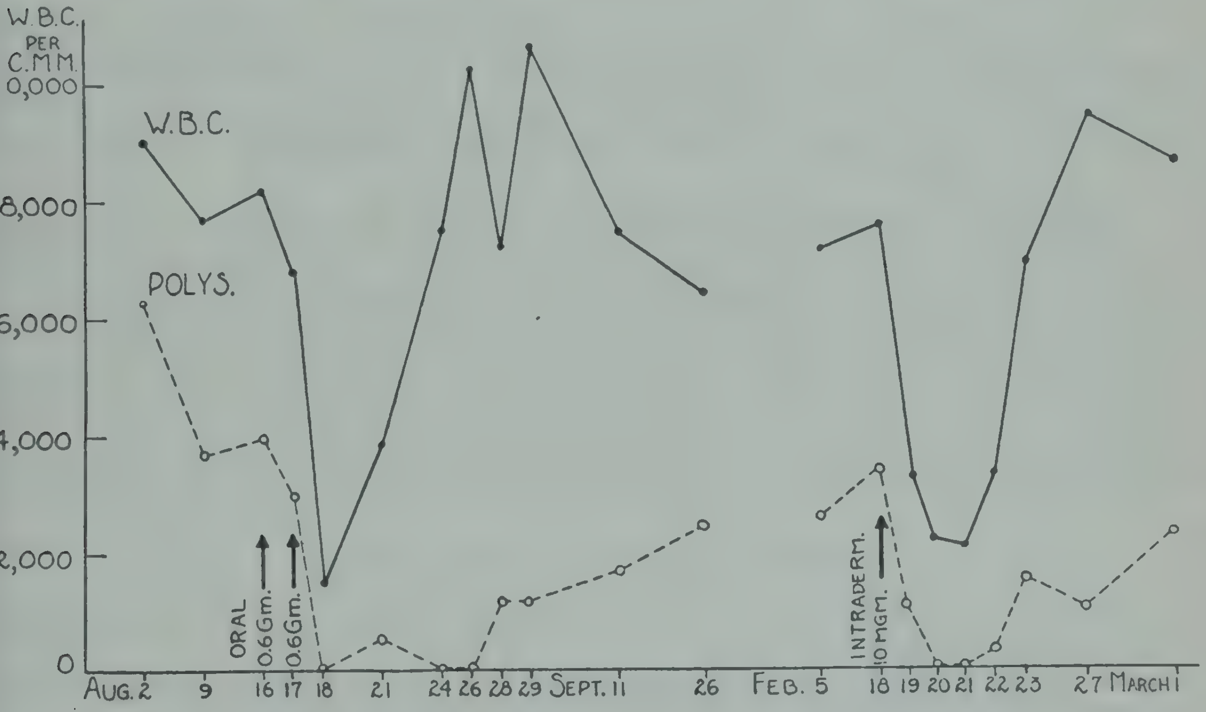


Figure 22. *Aminopyrine agranulocytosis.*

The patient was a woman, aged 49, who had had two previous attacks of agranulocytosis, at least one of which was due to aminopyrine. During a period of controlled observation, the patient ingested aminopyrine. First dose was taken at 7:00 P.M., Aug. 16th. Within 90 minutes severe headache, nausea, marked flushing of the face, malaise, weakness and joint pains were experienced. Second dose was taken on the following morning, and fever developed. Aug. 24th: Severe symptoms continued and ulcers were noted on the tongue and lips. Observe that the polymorphonuclear leukocyte count was only one per cent and that symptoms are related to agranulocytosis rather than to leukopenia. Patient did not feel better until Sept. 11th, when 25 per cent polymorphonuclear cells were present.

Scratch and intradermal tests with a five per cent solution of aminopyrine in distilled water were negative; but a positive reaction was obtained from a drug solution allowed to incubate with blood serum for several days before injection. The total amount of aminopyrine injected intradermally did not exceed 10 mgm, but the sequence of events which followed the oral ingestion of the drug was repeated. (After Dameshek and Colmes, 1936. Courtesy of the *Journal of Clinical Investigation.*)

The *mechanism of aminopyrine agranulocytosis* is unsettled. Animal experimentation has thus far not yielded a satisfactory answer. It is apparent that in certain sensitive individuals the drug can cause a maturation arrest of granulocytes in the bone marrow, and in such persons a minute amount may initiate the disease. Inasmuch as there is no certain or safe method of determining beforehand which patient will respond with agranulocytosis to aminopyrine, the question arises whether the drug should be used. It has been estimated that 30 million prescriptions alone were issued for this drug in the United States during the year 1934. When one adds to this the large "over-the-counter" sale of the chemical and of nostrums containing it, it can readily be appreciated that sensitivity is rare, because agranulocytosis is an uncommon disease. When the latter occurs, however, it is very serious and the mortality is high. For this reason and because aminopyrine is not indispensable, it is suggested that this drug not be used. As is the case with cinchophen, there is no "safe method" of administering the drug. The numerous warnings in the medical literature against aminopyrine have reduced considerably the prescribing of this drug. Whether the decline in agranulocytosis noted since 1933 is due to restriction in the use of aminopyrine is not known. It is instructive to note, however, that agranulocytic angina is unknown in Denmark where the medical profession has been induced to refrain from prescribing the drug.

The measures used in the *treatment* of agranulocytic angina are described elsewhere (page 1147). The patient should be warned against taking the drug, and told that there are numerous drug preparations and nostrums on the market which contain aminopyrine. A list of these drugs is presented by Hunter (1935) and Beckman (1938).

Many drugs containing aminopyrine are widely advertised for the relief of headache, dysmenorrhea and similar ailments, and are often dispensed by dentists for the relief of pain. It is interesting to note that a large number of the cases of aminopyrine agranulocytosis have occurred in nurses, technicians, physicians, and members of physicians' families. This is explained on the ground that samples of medicines containing aminopyrine sent to physicians by drug houses are readily accessible to these persons. The present control of the distribution and sale of aminopyrine by the Federal Food and Drug Administration is to be commended.

SECTION III

CENTRAL NERVOUS SYSTEM STIMULANTS

The central nervous system stimulants comprise a group of drugs which have in common the property of increasing the activity of various portions of the central nervous system. They differ markedly, however, both with respect to the locus and mechanism of this action.

Although the central nervous system stimulants are sometimes dramatic in their pharmacological effects, they are relatively unimportant from a therapeutic point of view. It is not possible to stimulate the nervous system over a long period of time, for heightened nervous activity is followed by depression, proportional in degree to the intensity and duration of the stimulation. Consequently, therapeutic excitation of the central nervous system is usually of brief duration and is reserved for emergencies characterized by severe central depression.

Another factor which limits the usefulness of the central stimulants is the multiplicity of their actions and the character of their side-effects. In this respect they are in marked contrast to the central depressant drugs which for the most part have a selective action on the nervous system. For example, caffeine not only stimulates the nervous system but also has a marked action on the heart, blood vessels and kidneys. Again, atropine and ephedrine stimulate the central nervous system but at the same time affect peripheral autonomic structures.

In this chapter, discussion will be limited to those drugs which have central stimulation as their predominant action, namely strychnine, picrotoxin, caffeine and related xanthines, coramine, metrazol and camphor. In addition to these agents, there is a large group of drugs whose property of central stimulation may be considered as secondary but important. These compounds include atropine, ephedrine, benzedrine, cocaine, nicotine, lobeline, carbon dioxide, cyanide, apomorphine, and emetine.

Finally, there are many drugs which, in toxic doses, temporarily stimulate the central nervous system. Compounds of this type are phenol, santonin, salicylates, local anesthetics, ergotoxine, etc. The central actions are described under the toxicology of these agents.

Whereas the number of drugs causing central excitation is large, the number employed clinically for this purpose is limited. Those which have special therapeutic value are the *respiratory* stimulants. In addition, central stimulants which act on the *vasomotor* or *vomiting* centers in the medulla have some usefulness. Lastly, there is a group of compounds known as *analeptics* which are employed to lessen narcosis. In some instances a single drug possesses several or all of the actions enumerated.

Although the therapeutic applications of the central stimulants are largely limited to their effects on the medulla, this is not the only site of action, for all portions of the cerebrospinal axis are affected by sufficiently large doses of the compounds.

Respiratory Stimulation. There are several physiological mechanisms by which stimulation of respiration can be accomplished. These are as follows: (1) the respiratory center can be stimulated directly either by drugs or by changes in the pH of the blood; (2) it responds readily to sensory impulses arising from the chemoreceptors of the carotid body; (3) the center is sensitive to afferent impulses, especially pain, coming from various parts of the body; (4) it also responds to the control exerted by the higher centers. The drugs which affect respiration act by one or more of these mechanisms. For example, caffeine stimulates the medulla directly. The locus of action of coramine, on the other hand, is on the carotid body. Reflex sensory stimulation of the medulla may be produced by local irritation resulting from the inhalation of ammonia or the subcutaneous injection of camphor, ether or alcohol. Ephedrine can stimulate respiration indirectly by lessening the degree of depression of the higher centers. Finally, a drug such as strychnine directly sensitizes the medulla to incoming stimuli and at the same time the analeptic action of the drug increases the number of effective impulses arising from other parts of the nervous system.

Vasomotor Stimulation. There are no drugs available which have a selective excitatory action on the vasomotor center but this portion of the medulla often shares in the general medullary stimulation produced by the respiratory stimulants and analeptics.

Stimulation of the Emetic Center. There are a few drugs which apparently have a selective action on the medullary vomiting center. These occasionally have some therapeutic application in the treatment of poisoning. The best example is apomorphine.

CHAPTER 15

STRYCHNINE AND PICROTOXIN

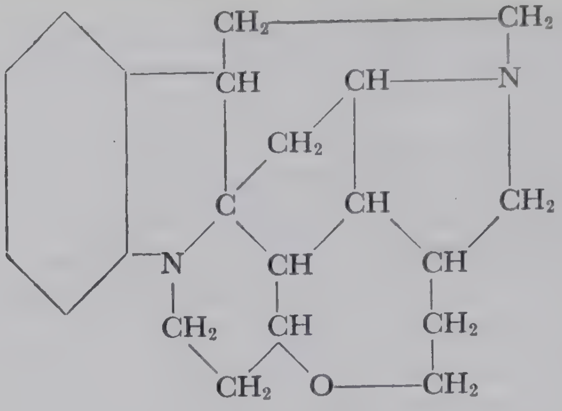
STRYCHNINE

Source. Strychnine is the principal alkaloid present in *Nux vomica,* the seeds of a tree native to India, *Strychnos nux vomica.* Nux vomica signifies "emetic nut." The origin of this name is puzzling, for strychnine is not emetic. It may have arisen through confusion with a nut of similar shape used by the Arabians for production of vomiting.

Nux vomica was introduced into Germany in the sixteenth century as a poison for rats and other animal pests. Its use as a rat poison persists to this day, and as an ingredient of "rat biscuits" strychnine is a source of accidental poisoning of children. Strychnine was first employed in medicine in 1540 but it did not gain wide usage until two hundred years later.

In addition to strychnine, the alkaloid *brucine* is found in nux vomica. Brucine, which is closely related to strychnine chemically, is much less active pharmacologically, and therefore the effects of extract of nux vomica are mainly due to strychnine.

Chemistry. Strychnine is an alkaloid of high molecular weight. It has the empirical formula $C_{21}H_{22}O_2N_2$ and the following probable structural formula (Achmatowicz and Robinson, 1938):



Strychnine

Pharmacological Actions

Central Nervous System. The outstanding action of strychnine is a stimulation of the central nervous system. All portions of the cerebrospinal axis are affected, but the predominant responses are referable to the functional changes produced in the spinal cord.

Spinal Cord. The action of strychnine on the spinal cord has been carefully studied and accurately localized. However, the exact mechanism by which the drug produces its characteristic effects is not fully understood. Strychnine in low dosage greatly increases the reflex excitability of the spinal cord. The result is that skeletal muscle responds in a coordinated but exaggerated manner. If the dose of strychnine is increased, all coordination is lost. Under such circumstances a minimal sensory impulse spreads diffusely up and down the cord instead of following a simple reflex arc and eliciting a discrete motor response. As a result of this spread, numerous voluntary muscles contract. The initiating sensory stimulus can be of any nature—auditory, visual, tactile, etc.

The simultaneous contraction of many muscles under the influence of strychnine leads to what is known as a *spinal convulsion.* In this type of convulsion reciprocal inhibition of antagonistic muscles is lost, and the final effect is determined by the stronger muscle groups. The spinal convulsion is also known as *symmetrical,* inasmuch as the contractions are bilateral and simultaneous, and *incoordinate,* for all coordination is lost in a tetanic type of response. The descriptive term *tonic* convulsion has likewise been applied.

Localization of Action. The localization of strychnine action to the spinal cord is readily demonstrable. As early as 1819, Magendie showed that strychnine spasms must be of central origin. He ligated the hind leg of a frog except for the sciatic nerve and then observed that the injection of strychnine into the ligated limb had no effect whereas the systemic administration of the drug produced a characteristic response even in the ligated leg. Other classical experiments have shown that the successive ablation of the cortex, subcortical motor centers and medulla do not prevent strychnine convulsions. The exact localization of action in the spinal cord proved to be more difficult. The problem to be solved was whether both the sensory and motor elements of the reflex arc must be poisoned by the drug in order that typical effects may be obtained. The most careful work in this field has been done by Dusser de Barenne who reviewed the entire subject in 1933. Dusser de Barenne applied strychnine solution directly to the spinal cord of mammals and observed the following reactions. When the drug was applied locally to the dorsal sensory area of a spinal cord segment, a well-defined response was elicited. It consisted of paroxysmal spontaneous paresthetic disturbances, hyperesthesia and hyperalgesia of the skin area receiving its innervation from the poisoned cord segment, a hypersensitivity of the corresponding deeper structures and a hyper-reflexia evidenced by irregular twitch-like contractions. Characteristic tetanus was not observed. On the other hand, if strychnine was applied to the ventral motor area of the spinal cord the response was limited to short twitch-like contractions of muscle without demonstrable tetanus. After applying strychnine both to the sensory and motor portions of the cord a characteristic tetanus resulted.

In Dusser de Barenne's most striking experiments, strychnine was first placed on the dorsal surface of the cord in the region of the arm segments. The sensory disturbances described were observed in the arm. The drug was then applied to the ventral surface of the cord in the region of the hind limb segments. Sensory stimulation of the hind limb led to no abnormal response, for the stimulus did not pass through a poisoned sensory area of the cord. On the other hand, sensory stimulation of the fore limb resulted in a tetanic contraction of the hind limb. Dusser de Barenne concluded, therefore, that strychnine must act on the cells of both the sensory and motor regions of the cord before it elicits characteristic responses.

Cortex. The action of strychnine is not limited to the spinal cord. The sensory cortex is also sensitized by the drug and as a result the senses of taste, touch and smell are made more acute. Visual acuity also improves after the administration of strychnine but some investigators believe that this may be due to a local effect on retinal cells rather than to a central action. In support of this view is the observation that the local administration of strychnine to one eye increases the visual acuity of that eye.

Medulla. Strychnine has a stimulating action on the medulla which would be useful in therapeutics were it not for the fact that large doses are necessary to produce it. Reflex hyperexcitability of the spinal cord always accompanies medullary stimulation by strychnine except in instances when the cord is depressed. The mechanism of action on the medulla is similar to that described for the spinal cord. It is probable that strychnine has no direct stimulating effect but rather sensitizes the medulla so that it responds in an exaggerated manner to the impulses which it is constantly receiving, and also to subminimal stimuli (Travell and Gold, 1935). When the term "strychnine stimulation" is used, it refers to this mode of action. The vasomotor and respiratory centers particularly manifest sensitization by strychnine. The drug in high dosage raises the blood pressure by central vasomotor stimulation. The elevation in blood pressure can be strikingly demonstrated in an animal curarized to prevent convulsions. Strychnine affects the respiratory center in an analogous manner. It is possible to antagonize with strychnine the medullary depression produced by toxic doses of barbiturates and other hypnotics. The spinal cord is usually sufficiently depressed under these circumstances to prevent strychnine convulsions.

In usual therapeutic doses, strychnine has no demonstrable effect on either the vasomotor or respiratory centers. This fact is often overlooked, and much of strychnine therapy is based upon the false premise that a small dose of the drug produces, in lesser degree, the same actions as a large dose.

Strychnine stimulation of the central nervous system is followed by depression. In fact death from strychnine poisoning is the result of respiratory failure resulting from medullary paralysis.

Peripheral Nerves. In very high dosage, strychnine has a depressant action on the transmission of impulses to skeletal muscle. This action can only be demonstrated in isolated nerve muscle preparations, for in the intact animal death supervenes before a sufficiently high concentration of strychnine can be reached. The site of action may be on the receptive mechanism of muscle rather than on nerve fibers. If this is true, strychnine may act in a manner similar to that of curare. In fact, some forms of curare have strychnine-like properties and are obtained from certain species of Strychnos plants.

Mechanism of Action. The mechanism of strychnine action on the central nervous system has been the subject of considerable investigation. Most theories are merely descriptive rather than explanatory. For example, the convulsive action has been ascribed to a lowering of chronaxie, a loss of reciprocal inhibition of antagonistic muscles, or a lowered resistance to the passage of impulses through the spinal cord.

The most illuminating contribution to the manner of strychnine action has been made by Heinbecker and Bartley (1939) who studied the effects of the alkaloid on the basic properties of nerve cell bodies and axons. Strychnine apparently acts similarly on all portions of the central and peripheral nervous system, but its greatest effect is on the cerebrospinal axis where the chief locus of action is directly on the nerve cell body. The drug lowers the threshold of excitability and diminishes accommodation (accommodation being the increase in threshold of excitability of a nerve due to a prolonged state of excitation). Also strychnine prolongs the period of latent addition, that is, the period after stimulation during which increased excitability persists. In other words, the alkaloid renders nervous tissue more excitable by three mechanisms—by lowering the threshold of excitability, by preventing the loss of excitability from continuous stimulation, and by prolonging the period of hyperexcitability which normally follows nerve stimulation but is usually of short duration. The ganglion cells of the central nervous system which are most markedly affected by strychnine are those possessing autochthonous rhythmicity and those which on excitation produce repetitive responses in their axons. Strychnine also exhibits its typical effects on the peripheral nervous system where it acts on axons, synapses and visceral ganglion cells. High concentrations of strychnine produce opposite effects by increasing the threshold of excitability.

It is of interest to observe that Nachmansohn (1938) has shown that strychnine *in vitro* inhibits cholinesterase in concentrations compatible with those causing convulsions *in vivo*. If it should be shown that acetylcholine is involved in central synaptic transmission (page 334), it is possible that strychnine produces its excitatory effects by preserving acetylcholine.

Cardiovascular System. Strychnine has no important action on the cardiovascular system and there is no basis for its use as a stimulant for a failing circulation. The drug has no peripheral effect on the heart or on the blood vessels. It is possible to stimulate the isolated perfused heart with strychnine, but the concentration necessary to evoke this response is far in excess of that obtained clinically. In high doses, strychnine raises the blood pressure, but this action has no therapeutic significance inasmuch as it is of central origin and the response is always accompanied by convulsions unless the spinal cord is depressed. When a therapeutic dose of strychnine is administered to man, no consistent blood pressure response can be observed.

Gastro-intestinal Tract. Strychnine has an undeserved reputation as a drug capable of stimulating the smooth muscle of the gastro-intestinal tract. The action of strychnine on the intestinal musculature was first brought into prominence by the work of Langley and Magnus (1905). These investigators studied the action of the drug applied directly to the intestine of anesthetized animals or to isolated intestinal strips. They reported that strychnine was a definite stimulant to intestinal activity. It is this work which has largely been responsible for the therapeutic use of strychnine for atonic constipation and in cathartic combinations. Yonkman (1929), working with unanesthetized dogs with intestinal fistulas, also came to the conclusion that strychnine increased all phases of muscular activity of the intestine without causing an increase in reflex excitability of the nervous system. Gruber, Bryan and Richardson (1932) have taken exception to the aforementioned results. From their animal experiments they concluded that strychnine is of questionable value as an intestinal stimulant and that it is impossible to interpret accurately tracings obtained from intestinal movements due to associated skeletal muscle contractions caused by the drug. Furthermore, experiments on patients with intestinal fistulas at various levels have failed to indicate any effect of strychnine medication on the motility or tone of the human bowel. For example, Yonkman and Singh (1934) reported that strychnine in doses of two to three mgm had little or no effect in promoting the activity of the human colon as tested in patients with colostomies (Figure 23). Thus, the action of strychnine on the gastro-intestinal tract is not such as to recommend the drug as a therapeutic agent.

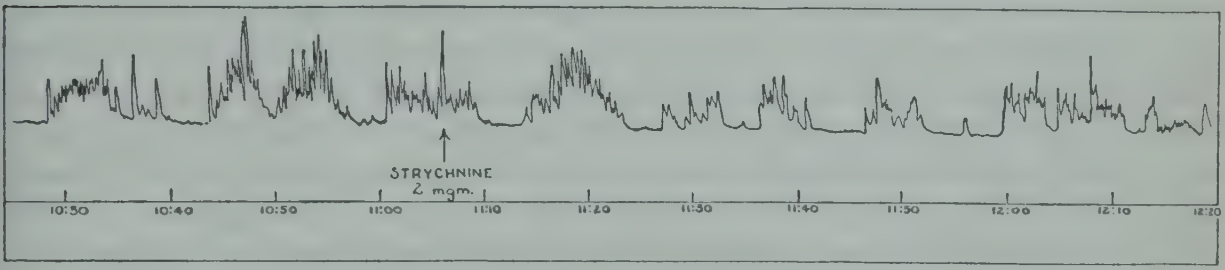


FIGURE 23. *The inefficacy of strychnine as a stimulant of the intestinal musculature in man.* The kymographic tracing was obtained by means of a balloon inserted through a colostomy into the large intestine of a patient. The balloon was connected through a water manometer to a modified Brodie air bellows. The intramuscular injection of two mgm of strychnine sulfate had no demonstrable effect on the tone or motility of the colon. (After Yonkman and Singh, 1934. Courtesy of *The Journal of the American Medical Association.*)

Strychnine is an intensely bitter substance, its taste being detectable in aqueous dilutions of 1:100,000 to 1:400,000. The drug is therefore used as a stomachic and bitter. Bitters supposedly stimulate the taste buds, increase the appetite, and reflexly stimulate gastric secretion.

Skeletal Muscle. Therapeutic doses of strychnine have no direct action on skeletal muscle. The increased tone and activity of voluntary muscle which is observed to follow strychnine administration is exclusively the result of the action of toxic amounts of the drug on the central nervous system.

Absorption, Fate and Excretion. Strychnine is readily absorbed from the gastro-intestinal tract and parenteral sites of injection. It is carried in the blood by both the serum and cells and rapidly leaves the circulation for the tissues. The central nervous system does not contain a higher concentration of the drug than do other organs. Strychnine is readily destroyed in the body, mainly by the liver. Approximately 20 per cent of the alkaloid escapes into the urine. Urinary excretion of the drug starts within a few minutes after administration and is practically complete within 10 hours, although traces may be found for several days.

The rate of destruction of strychnine is such that approximately two lethal doses can be given over a period of 24 hours without noticeable toxic symptoms or cumulative effects. The toxic dose after subcutaneous administration is only one-half to one-third that of the oral dose.

Tolerance. Tolerance to strychnine does not develop. In fact it has been claimed that with continued administration of the drug the central nervous system becomes sensitized to its action.

Toxicology. Poisoning by strychnine is not rare. The drug is not employed as a suicidal agent as often as formerly, mainly because the central nervous system depressants are at present in favor. The incidence of accidental strychnine poisoning in children, however, is surprisingly high (Aikman, 1930; Ross and Brown, 1935). The sugar-coated A.S. and B. cathartic pills (N.F.) have been the cause of a number of these accidental strychnine poisonings.

The symptoms of strychnine poisoning are mainly those of central nervous system stimulation. The first effect is noticed in the muscles of the neck and face where a definite stiffness is felt. This is followed by heightened reflex activity. The slightest stimulus causes a violent response which in the early stages of poisoning is coordinate in character. As the action of the drug proceeds, spontaneous muscle twitchings occur. A mild sensory stimulus may now precipitate a typical spinal convulsion. The movements at first are intermittent, but after a few seconds spinal tetanus appears, involving all muscles in a symmetrical fashion. Inasmuch as the stronger muscles always predominate, a typical posture ensues. In man, the body is arched in hyperextension (opisthotonos) so that only the crown of the head and the heels of the patient may be touching the ground. The legs are adducted and extended and the feet turned inward. The arms may be strongly flexed over the chest or rigidly extended. The fists are clenched. The jaw is rigidly clamped and the strong contraction of the facial muscles produces a hideous grin which has been called *risus sardonicus*. The diaphragm is involved in the general muscular contraction and this, coupled with the spasm of the thoracic and abdominal muscles, arrests respiration. Exophthalmos, mydriasis, and cyanosis also occur.

To appreciate the subjective feelings of an individual during a strychnine convulsion, one need only recall that strychnine stimulates the sensory cortex and that the patient is not only conscious but unusually appreciative of all sensations accompanying the violent muscular activity. The muscle contractions are quite painful and the patient remains acutely apprehensive and fearful of impending death throughout the ordeal.

The convulsions last approximately a minute or more after which the muscles relax and respiration is resumed. A period of depression follows the convulsion. If the convulsion has been an unusually long one, the patient may be rendered unconscious due to the apnea and anoxemia. During the period of depression, reflex irritability is low. A second convulsive seizure usually follows the first by not more than 10 or 15 minutes. Death commonly follows the second to fifth seizure, but it may ensue from the initial convulsion. Death results from medullary paralysis. This is due not only to excessive stimulation but also to anoxia resulting from the apnea.

Treatment of Strychnine Poisoning. The object of therapy in strychnine poisoning is to prevent convulsions and protect the medulla from anoxia and excessive stimulation. By the use of central nervous system depressants it is possible to antagonize the action of strychnine and abolish completely all abnormal motor activity. Formerly, morphine was commonly employed for this purpose. This was an unfortunate choice because morphine is depressant to the medulla and also heightens reflex excitability of the cord. Rational therapy requires the use of the barbiturates in strychnine poisoning. There is such a marked degree of antagonism between the actions of strychnine and the barbiturates that under laboratory conditions it is possible to protect animals from thirty-five minimal lethal doses of strychnine. Barbiturates depress hyperexcitability of the spinal cord and their depressant action on the higher centers also blocks many stimuli entering the cord from above. The barbiturates thus protect the medulla mainly by preventing strychnine convulsions. In addition, they counteract excessive excitability of the medulla itself.

It is obvious that when two antagonistic drugs are so balanced with respect to intensity of action on a particular vital center, the removal of one of them would lead to an unchecked and probably toxic action of the other. Therefore, in treating strychnine poisoning with a barbiturate, it is essential to select a preparation that has a duration of action no longer than that of the poison itself. Inasmuch as strychnine is destroyed with moderate rapidity, the preparation of choice is a short-acting barbiturate. If its action wears off too soon, more of the drug can be given. In this way, the reflex excitability of the central nervous system can be maintained within fairly normal limits until the strychnine has been completely detoxified and excreted.

The first step in the therapy of strychnine poisoning is the intravenous injection of a soluble short-acting barbiturate. Evacuation of the stomach must be postponed because the passage of a stomach tube or administration of an emetic may precipitate a convulsion. The sodium salts of both pentobarbital and amytal are very effective. The route of injection is usually intravenous for rapidity of action is essential inasmuch as each succeeding convulsion greatly reduces the patient's chance for recovery. The barbiturates are injected slowly, 10 per cent solutions usually being employed. The dose of sodium amytal is from 0.4 to 1.0 gram, and of pentobarbital-sodium, 0.3 to 0.7 gram. However, one cannot be dogmatic about dosage. The drug should be injected until the desired condition is obtained, namely, a degree of depression sufficient to antagonize convulsions and keep the patient asleep, and yet not so deep as to depress respiration or blood pressure.

Gastric lavage may now be performed if there is a possibility that some of the poison still remains in the stomach. Potassium permanganate is an effective chemical antidote and may be used for gastric lavage in a 1:1000 concentration. Tincture of iodine diluted with water (1:250) or tannic acid solution (2.0 per cent, or in the form of strong tea) may also be employed.

The patient should be kept under careful observation for many hours and protected from all possible stimuli. Wakefulness, muscle twitchings and increased reflex excitability are the signs that warn of the necessity for additional barbiturate. On the other hand, if excessive amounts of barbiturate have been given, it may be necessary to administer a respiratory stimulant or artificial respiration.

Central depressants other than the barbiturates may be employed in strychnine poisoning if barbiturates are not available. The inhalation anesthetics may be used temporarily to control convulsions until a barbiturate can be obtained. Chloroform is preferred because it is more potent and less irritating than ether. Chloral hydrate or paraldehyde may also be given. Avertin has been successfully employed.

The barbiturates have the distinct advantage of rapidity of onset of action and ease of administration.

Preparations. The official commonly employed preparations of strychnine are as follows: *Tincture of Nux Vomica,* U.S.P., contains 1.1 to 1.2 mgm of strychnine in each cc.; B.P., 2.5 mgm in each two cc. Its dose is 0.6 to 1.0 cc. *Extract of Nux Vomica,* U.S.P., contains about 7.5 per cent strychnine. Its dose is 15 mgm. *Dry Extract of Nux Vomica,* B.P., contains five per cent strychnine. The salts of strychnine are *Strychnine Sulfate,* U.S.P., *Strychnine Nitrate,* U.S.P., and *Strychnine Hydrochloride,* B.P. All possess the characteristic physical properties of alkaloids. The dose of either is one to two mgm. Strychnine in combination with iron and quinine (*Elixir of Iron, Quinine and Strychnine,* N.F.) is an irrational and complex mixture commonly employed as a tonic. Its dose is four cc.

Therapeutic Uses. Strychnine has an undeserved reputation as a useful therapeutic agent. To the drug have been ascribed properties which it does not possess or exhibits only when administered in toxic doses. Pharmacological studies have shown that many of the therapeutic applications of strychnine have little or no rationale; yet, like alcohol, the drug has a background of long usage and it continues to enjoy unwarranted popularity.

Strychnine is extensively employed as a *tonic.* This "tonic" effect is supposedly comprised of three aspects of strychnine action—the bitter taste, stimulation of the gastro-intestinal tract, and an increase in tone of voluntary muscle. As a bitter, strychnine is in no way unique. The remaining two actions are not manifested by therapeutic doses. Indeed, it is questionable whether the drug affects the motility of the enteric tract at all. The practice of administering strychnine intramuscularly as a tonic can only be censured, for even if the drug were of therapeutic value absorption following oral administration is both adequate and rapid. Parenteral therapy, in addition, is inconvenient and expensive.

Strychnine is sometimes used to *increase skeletal muscle tone* in unconscious patients, as for example, immediately following general anesthesia. Strychnine, however, enhances muscle tone only in doses just short of the convulsive, for this response is dependent upon stimulation of the spinal cord. In the doses usually employed, the drug is inactive. This is fortunate because an effective amount would endanger the patient.

There is no rational basis for the employment of strychnine in lesions of the *nervous system.* Stimulation by strychnine has no beneficial influence on any infectious, toxic, traumatic, or vascular lesion of the brain, spinal cord or peripheral nerves.

The action of strychnine on the *cardiovascular* system does not warrant its use in circulatory disorders. Any effect which strychnine has on the circulation is the result of central vasomotor stimulation and this is observed only when convulsive doses of the drug are given.

Strychnine is a valuable *respiratory stimulant* when the central nervous system is depressed to a degree which allows effective doses to be given with safety.

Consequently, strychnine is useful in the treatment of poisoning by the central nervous system depressants, especially the barbiturates (page 142).

PICROTOXIN

Picrotoxin is obtained from the *Cocculus indicus,* a climbing shrub indigenous to Malabar and the East Indies. The drug is present in the berries of the plant, commonly known as fishberries, a name derived from the native practice of throwing the bruised berries upon the water as a means of catching fish. The fish, after devouring the berries, are incapacitated and rise to the surface.

Chemistry. Picrotoxin is a non-nitrogenous neutral principle having the empirical formula $C_{30}H_{34}O_{13}$. It can be broken down to *picrotoxinin,* an active substance resembling picrotoxin in its pharmacological properties, and *picrotin* which is inactive.

Pharmacological Actions. *Central Nervous System.* Picrotoxin is a powerful central nervous system stimulant. Its site of action is higher in the cerebrospinal axis than is that of strychnine. In mammals, picrotoxin stimulates the cortex although its most prominent effect is on the midbrain and medulla. With large doses, the cord is also affected.

In an unanesthetized animal or man, the actions of picrotoxin are purely toxic. No appreciable effect is seen until convulsive doses are given. Then all portions of the central nervous system seem to share in the stimulation; confusion followed by unconsciousness indicates that the drug first stimulates and then depresses the cortex. The actions of the drug are most prominent on the lower centers, especially the medulla. The vomiting, respiratory and vasomotor centers are all stimulated. Salivation and emesis commonly occur. Vasomotor stimulation results in an elevated blood pressure. At the same time, however, there may be central vagal stimulation which markedly slows the heart. Initial respiratory stimulation is quite evident.

In large doses, picrotoxin causes convulsions. In mammals picrotoxin convulsions are altered in character by ablation of the cortex and disappear after destruction of the pons. Inasmuch as they arise from the higher centers, they are quite coordinated. Such a convulsion, in contrast with the type produced by strychnine, has been termed asymmetrical, clonic, and coordinated. Reciprocal innervation is not lost, and the limbs are alternately extended and flexed. Eventually the stimulation of the central nervous system produced by picrotoxin is followed by depression. Death results from respiratory failure.

Picrotoxin Antagonism of Central Depressant Drugs. One of the most interesting actions of picrotoxin, first mentioned by Maloney, Fitch and Tatum (1931), is its ability to combat the central depression which results from the administration of high doses of barbiturates. This analeptic action is striking and one can protect experimental animals against toxic doses of the barbiturates by the use of picrotoxin. The drug is the most effective of all the central nervous system stimulants in this respect (Das, 1939). In clinical poisoning by the barbiturates, the drug reinstates adequate respiration and greatly lightens the degree of anesthesia.

The stimulating effect of picrotoxin on depressed respiration has been studied especially by Marshall and coworkers (1937). These investigators observed that picrotoxin stimulated the respiration in anesthetized animals but in normal or decerebrate animals convulsive doses had to be given before any respiratory effects were obtained. The drug was effective in combating the depressant actions of chlorbutanol, paraldehyde and avertin, but was quite useless in alcoholic depression. They concluded that the action of the drug was not directly on the medulla, but rather that it stimulated respiration indirectly by decreasing narcosis.

Koppanyi and coworkers (1936) studied the effect of picrotoxin in experimental morphine poisoning. They observed that, although picrotoxin temporarily supported the respiration and circulation in morphine-poisoned animals, the stimulating action of morphine on the cord so combined with the central stimulation of picrotoxin that the two drugs were synergistic in producing convulsions. Thus the minimal lethal dose of morphine was lowered by picrotoxin.

Absorption, Fate and Excretion. Although picrotoxin is absorbed from all channels, it is usually given intravenously. Following its intravenous administration to experimental animals, the drug rapidly leaves the circulation and after 20 minutes only traces can be detected in the blood (Duff and Dille, 1939). Its distribution in the body is unknown. Picrotoxin is probably destroyed quite readily and this accounts for the clinical practice of administering small doses frequently for a sustained effect. If very large amounts are injected, a portion can be recovered in the urine.

Toxicology. Picrotoxin is a highly toxic substance and a dose of 20 mgm may produce symptoms of severe poisoning. The fatal dose for human beings is unknown. The symptoms of picrotoxin poisoning are those described under its central actions. A barbiturate is the best antidote for poisoning by picrotoxin and the procedure outlined for the treatment of strychnine poisoning, except for the use of chemical antidotes, applies also to picrotoxin.

Preparations. Picrotoxin is not an official drug, and preparations are not readily available. It can be obtained, however, in the form of the crystalline compound.

Therapeutic Uses. The only therapeutic use for picrotoxin is in the treatment of poisoning by the central nervous system depressants, notably the barbiturates. Although the drug has but a short clinical history, favorable reports have appeared in the literature and from the available evidence it appears that picrotoxin may be an effective physiological antagonist to the barbiturates.

In the treatment of *barbiturate poisoning*, picrotoxin is administered by intravenous injection. No didactic statement regarding dosage can be made. Rather the drug is given until the return of the corneal and pupillary reflexes. Bleckwenn and Masten (1938) recommend that the drug be injected in a 1:1000 concentration in isotonic saline solution at the rate of one cc (one mgm) a minute until the desired effect on reflex activity is obtained. Repeated injections may be necessary if the patient again relapses into a deep narcosis. However, consciousness may remain in abeyance despite the return of reflexes (Rovenstine, 1938). An individual poisoned with a barbiturate is often extremely tolerant to picrotoxin and during treatment usually receives amounts of the drug which would be fatal to a normal individual. Total doses often range between 50 and 150 mgm given over a period of several hours. Kohn and coworkers (1938) report the successful treatment of a case of barbiturate poisoning with a total of 671 mgm of picrotoxin.

From laboratory evidence it is possible that picrotoxin may prove of value in the treatment of poisoning from central depressants other than the barbiturates. However, it seems to be contraindicated in the treatment of morphine poisoning as also is strychnine.

Therapy of barbiturate poisoning should not be limited to the injection of picrotoxin. Other drugs and supportive measures are also indicated (page 142). The status of the use of picrotoxin in poisoning by the barbiturates has been reviewed by the Council (1939), and by Reifenstein and coworkers (1939).

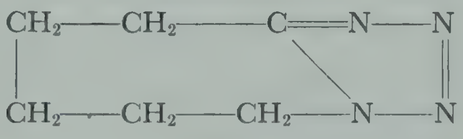
CHAPTER 16

METRAZOL, CORAMINE AND CAMPHOR

METRAZOL

Metrazol (cardiazol) is a synthetic compound which possesses to a high degree the property of stimulating the central nervous system. Chemically, it is related to camphor inasmuch as in metrazol the six carbon ketone ring of camphor has been condensed to form pentamethylenetetrazol. The structural formula is as follows:



Metrazol

Pharmacological Actions. *Central Nervous System.* Metrazol is a central nervous system stimulant. Its action is primarily on the higher centers but all parts of the cerebrospinal axis are stimulated to some degree. When given in high dosage to experimental animals, metrazol first causes marked restlessness which is followed by excitement, increased motor activity and typical epileptiform convulsions. The convulsions can still be elicited after removal of the cerebrum above the thalamus. With successive ablation of lower segments of the brain stem, the convulsive dose of metrazol becomes greater.

The medulla also shares in the stimulation. Respiration is markedly increased by large doses of metrazol. The vasomotor and vagal centers of the medulla are likewise stimulated.

The reflex activity of the cord is increased. In fact, when large amounts of metrazol are administered, the epileptiform convulsions may terminate in typical tonic convulsions. The action of metrazol on the spinal cord is especially evident if the reflex activity of the cord has been lowered by central nervous system depressants. In such a case, a relatively small dose of metrazol will restore spinal reflexes toward normal. There appears to be a definite limit in the ability of metrazol to restore to normal the functions of the depressed spinal cord. Koll (1937) noted that once the maximal action of the drug was obtained, it could not be enhanced by the injection of additional amounts. However, if strychnine were now injected, a further increase in reflex activity was obtained. Likewise, Koll observed that metrazol was capable of increasing reflex excitability after strychnine had been allowed to exert its maximal effect.

The analeptic action of metrazol on the higher centers of the central nervous system is evident from its ability to counteract the depression produced by hypnotic drugs. This is prominent when directed against the depression caused by barbiturates, avertin, paraldehyde and chloral hydrate. So marked is the antagonism of metrazol to avertin that experiments have been described in which animals with complete motor paralysis have been restored to normal immediately after the administration of metrazol. Not only is motor activity restored, but failing respiration and circulation are stimulated through the medullary action of the drug. The effect of metrazol on the medulla is much more prominent when this region is depressed than when it is functioning normally. The action is probably a direct one for typical effects on blood pressure and respiration can be obtained after the carotid sinus and carotid body have been completely denervated. As a result of this analeptic action, metrazol can protect against toxic doses of central depressants. Likewise, individuals depressed by hypnotics (*e.g.,* amytal) are more resistant to the actions of metrazol (Cohen, 1939).

Circulation. Metrazol has been widely heralded as a circulatory stimulant but its peripheral action on the heart and blood vessels is negligible. It has no definite cardiac effect when perfused through the isolated mammalian heart. Neither does it improve the coronary circulation to a significant degree. It has no constrictor action on the musculature of blood vessels. Indeed, the drug may produce splanchnic vasodilatation (Haury and Gruber, 1939). The cerebral vessels are also dilated by metrazol (Forbes and Nason, 1940). Clinically, the circulatory effects of metrazol are due entirely to its action on the medulla. When the circulation has been depressed by a hypnotic agent, a marked rise in blood pressure can be noticed after the injection of metrazol as a result of central vasomotor stimulation. However, when the drug is given to a normal individual or to a patient whose circulation is depressed by other than central mechanisms, no such response is obtained. Indeed, the pressure may fall due to the bradycardia which results from central vagal stimulation.

Messinger and Moros (1940) studied the cardiovascular effects on human beings of convulsive doses of metrazol as employed in the treatment of schizophrenia. No pronounced or prolonged alterations in blood pressure could be attributed to the action of the drug. In some instances transitory cardiac irregularities, most often auricular extrasystoles and sinus arrhythmia, were observed. Rarely were ventricular extrasystoles noted. Messinger and Moros conducted their investigations primarily to establish whether metrazol was contraindicated in the treatment of schizophrenic patients with organic heart disease. So innocuous were the effects of large doses of the drug on the cardiovascular system that they concluded that metrazol was of little value as a cardiac stimulant.

Toxicology. Metrazol is a relatively non-toxic drug insofar as the amount necessary to produce serious poisoning is concerned. Two hundred milligrams may be given intravenously in human beings without danger. Death has been reported from the ingestion of 10 grams. The symptoms are typical of those produced by the central nervous system stimulants having actions on the higher motor centers and the spinal cord, and consist of clonic and tonic convulsions. The convulsions are spontaneous in origin and not induced by external stimuli. They last for several minutes and are followed by profound depression. Death results from anoxemia, medullary depression and respiratory paralysis.

The repeated injection of convulsive but non-fatal doses of metrazol in experimental animals (three times weekly for a total of 14 to 18 injections) causes pathological changes in the brain (Whitehead and coworkers, 1940). The lesions consist of diffuse degenerative changes of moderate degree in nerve cells and complete necrosis of the nervous parenchyma in circumscribed areas of the cortex.

The lesions are attributable to the periods of cerebral anoxia which attend metrazol convulsions.

Metrazol Convulsions in Man. Metrazol has been extensively employed in the treatment of schizophrenia, and this has offered the opportunity to study metrazol convulsions under controlled conditions. The observations of Finkelman and coworkers (1938) on metrazol convulsions in man are quoted verbatim because, in a broad sense, they apply to the actions of any drug capable of stimulating the brain and cord and producing both clonic and tonic convulsions.

"From two to five seconds after the intravenous administration of metrazol the patient coughs, and five seconds later marked pallor of the face occurs. From three to ten seconds after the injection an intense blepharospasm occurs and the facial expression is a mixture of bewilderment and fear. Five seconds later myoclonic convulsive movements begin in the face, shoulders and arms, sometimes only on one side. A well marked rhythmic clonic phase develops. . . . After about fifteen seconds a tonic phase ensues. The head is retracted and the back arched. The eyeballs may move upward or to either side or remain in the original plane. The arms and legs are tetanically contracted in extension. The wrists and fingers are flexed, the position of the thumb frequently being between the index and the middle finger. Sometimes before the opisthotonos there is a flexion of the thighs, legs and feet, with the large toes in the Babinski position. This is followed by an extension of the lower extremities. Frequently there is an adductor spasm, with the legs in a scissor-like position. These positions of the body may change during the tonic phase; the knees may be flexed on one side and extended on the other. There may be a rotation of the pelvis to one or the other side, with flexion of the thighs and legs, followed by an extension. Similarly, the upper extremities may assume various postures.

"The tonic phase lasts from five to thirty seconds and is followed by another clonic phase. The first clonic movements break through in the fingers and spread to involve the entire body. Such rhythmic clonic movements are seen while the extremities are still held in tonic extension. The clonic movements are at first rapid, gradually become less frequent with increasing amplitude and cease after about twenty-five seconds. During this stage ejaculation may occur. Urination is observed after relaxation. During the tonic phase and the succeeding clonic one, there is a period of apnea, with marked cyanosis. After a few seconds the patient resumes breathing. A pilomotor reaction is present during the tonic phase and gradually disappears during the apneic period. Sometimes the lower extremities and not infrequently the upper extremities are rigidly extended after the second clonic phase. After the convulsion the patient frequently is drowsy and may fall asleep. About one minute after the last clonic phase a period of restlessness may occur. The patient may thrash his arms about, or there may be a definite pattern of movements, such as rolling of the body to the side. About five minutes after the injection the patient's attention may be attracted by verbal stimuli. As a rule each individual has his own constant motor pattern. The patient may show some motor restlessness immediately before the first clonic phase, such as flapping his arms as in 'wing beating,' brushing his face or alternately raising or lowering legs.

"In the majority of cases there is a short period of areflexia soon after the convulsion, which is followed in a few seconds by increased deep reflexes, sustained ankle clonus and the Babinski sign. Usually there is a short period of confusion after the seizure. In some patients the confusion may last several hours. The patient has total amnesia for the phenomena, recalling only the injection and a feeling of anxiety. One patient counted to thirty after the injection but after the reaction stated that he recalled counting only to twelve.

"The pupils are dilated during the convulsion and do not react to light. In some cases there is profuse perspiration after the convulsion. The blood pressure rises from 20 to 60 mm. of mercury during the seizure and drops to its normal level in from ten to thirty minutes."

Absorption, Fate and Excretion. Metrazol is rapidly absorbed from all sites of administration. Indeed, so rapid is its absorption that there is slight difference in the latent period before its action appears after peroral, subcutaneous and intravenous administration. Metrazol is also very rapidly detoxified, probably by the liver, and in experimental animals 50 per cent of a convulsive dose can be given at two hour intervals without eliciting toxic symptoms. The clinical action of metrazol is thus evanescent. The metrazol molecule is stable, a fact suggesting that the drug is detoxified by conjugation rather than by destruction. Metrazol cannot be demonstrated in the urine in an unchanged or active form.

Preparations. *Metrazol,* N.N.R., is a white crystalline powder soluble in water. It is available in 100 mgm tablets and as a 10 per cent solution, either in bulk for oral administration or in sterile ampules containing one cc (100 mgm) or three cc (300 mgm).

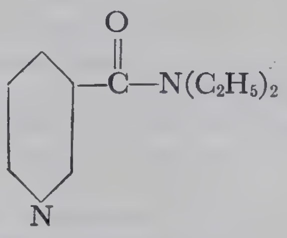
Therapeutic Uses. Metrazol is recommended as a central nervous system and cardiovascular stimulant. It is of value in the *treatment of poisoning by central depressants* but is probably less effective than strychnine, picrotoxin, caffeine or ephedrine. The drug, however, is rapidly detoxified and therefore its action can be well controlled. Metrazol has also been employed as an *analeptic* to lessen the degree of anesthesia. Pharmacological evidence does not encourage the use of metrazol as a cardiovascular stimulant. It is of doubtful value in circulatory collapse other than that due to central vasomotor depression, and is not indicated in shock. The dose usually employed for parenteral administration is 0.1 to 0.3 gram (one to three cc).

Metrazol has been used in the treatment of *schizophrenia.* The drug is given intravenously in amounts sufficient to cause convulsions (usually from three to seven cc). It is claimed that remission of symptoms in a fair percentage of cases follows a course of metrazol convulsions. It is impossible to state the exact mechanism of action (*see* insulin convulsions, page 1225) or properly to evaluate the true worth of the drug in mental disorders. The procedure involves definite risks to life, and should be undertaken only by psychiatrists especially trained in this field. The acute anterior flexion of the body induced by the metrazol convulsion may cause a high incidence (22 cases in 51 patients) of compression fractures of the thoracic vertebrae (Polatin and coworkers, 1939). Similar observations have been recorded by Bennett and Fitzpatrick (1939) and Hamsa and Bennett (1939).

CORAMINE

(NIKETHAMIDE)

Coramine is a pyridine derivative with the following structural formula:



Coramine

The compound is a synthetic, water-soluble, light viscous oil which was introduced into therapeutics as a respiratory and cardiac stimulant.

Pharmacological Actions. *Central Nervous System:* Coramine is a respiratory stimulant and apparently exerts this effect in doses which have little action on other portions of the cerebrospinal axis. Respiration is stimulated reflexly by the effect of coramine on the chemoreceptors of the carotid body. In toxic amounts, coramine causes convulsions from excitation of higher motor centers. Following toxic doses, death results from respiratory paralysis. Coramine acts more powerfully on a depressed than on a normal respiratory center. It is claimed that the drug is of particular value in overcoming the respiratory depression caused by morphine (Maloney and Tatum, 1932). Coramine is also said to be more effective against the depression of respiration caused by volatile anesthetics than that produced by large doses of barbiturates.

In addition to its action on the respiration, coramine acts as an analeptic. It counteracts the anesthetic action of a variety of the central nervous system depressants, and is particularly effective in overcoming the depressant action of avertin. There is some laboratory evidence that the duration of action of the barbiturates is not shortened by coramine, but clinical data seem to indicate that the drug arouses patients from barbiturate depression. However, coramine is less effective in this respect than picrotoxin or metrazol (Burstein and Rovenstine, 1937).

Circulation. The effects of coramine on the circulation are not striking. The drug supposedly stimulates the heart muscle directly, increases coronary blood flow, and causes peripheral vasoconstriction by central vasomotor stimulation. It is also claimed to have a direct effect on the capillary walls. However, there are many investigators who have failed to observe these cardiovascular actions. The drug is probably only of benefit in treating circulatory depression of central origin.

Absorption and Route of Administration. Coramine is absorbed from all sites of administration. However, it is most effective after intravenous injection. The drug has a wide margin of safety, and in laboratory animals the toxic dose is ten times the minimal effective dose.

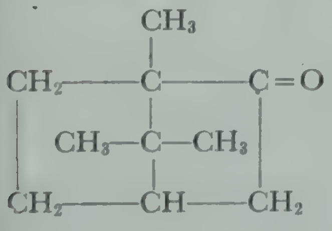
Preparation and Dosage. Coramine is neither an official preparation nor is it included in N.N.R. However, the Council has assigned to the compound the non-proprietary name "nikethamide." It is available in 25 per cent aqueous solution marketed in bulk for oral use and in sterile ampules for parenteral administration. The dose by any route is one to three cc.

Therapeutic Uses. The main therapeutic use of coramine is as a *respiratory stimulant* in the event of excessive depression following the use of central depressants. It does not compare in efficiency with strychnine, metrazol, picrotoxin or caffeine. Coramine, despite its name, is of little value as a cardiovascular stimulant and should not be the drug of choice in combating combined circulatory and respiratory depression. It is of interest to note that coramine, as well as other derivatives of nicotinic acid, has proved effective in the therapy of *pellagra* (page 1255).

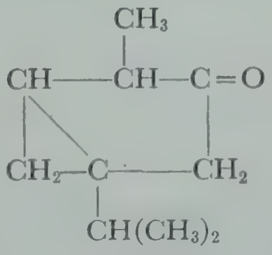
CAMPHOR

History. Camphor has been used for centuries in Chinese medicine for a variety of purposes. It was probably the odor of the compound which led to its use as a medicinal and for the same reason it has today some reputation among the laity as a valuable agent for protection against infection. Some children are still required by their parents to wear camphor bags suspended around their necks to ward off colds and other ailments.

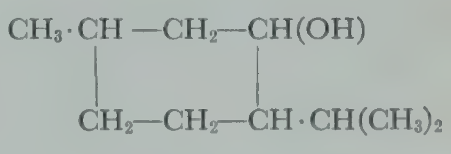
Chemistry. Camphor belongs to a group of substances known as the stearoptenes. These are crystalline compounds which are deposited from volatile oils upon standing, especially when exposed to cold. Natural camphor is obtained from the wood and bark of a tree, *Cinnamomum camphora*, growing especially in Japan and Formosa. Camphor is also obtained synthetically. Related to camphor are menthol, obtained from oil of peppermint, and thujone, an isomer of camphor which occurs in absinthe. Thujone is not used therapeutically but it has been claimed that it may cause the epileptiform convulsions occurring in chronic absinthe drinkers. The structural formulas of these three substances are as follows:



Camphor



Thujone



Menthol

Pharmacological Actions. *Local.* Locally, camphor is weakly antiseptic. It is also a rubefacient when rubbed on the skin. When not vigorously applied, however, it may produce a feeling of coolness. This is especially true of menthol. The sensation is quite noticeable in the respiratory tract when low concentrations of menthol are inhaled, as in the smoking of mentholated tobaccos. The mechanism of this action is imperfectly understood but it is thought to be due to selective stimulation of nerve endings sensitive to cold. Camphor also has a mild local anesthetic action and its application to the skin may be followed by numbness.

Camphor has a local action on the gastro-intestinal tract. It has a hot, bitter taste and when taken in small amounts produces a feeling of warmth and comfort in the stomach. In large doses it is irritating and causes nausea and vomiting.

Central Nervous System. Camphor stimulates the central nervous system. In man and mammals this action is more marked on the higher centers, although all portions of the cerebrospinal axis share it to some degree. In high doses the drug produces epileptiform convulsions which are largely cortical in origin.

The effects of non-convulsive doses of camphor on the respiration are negligible. In cases of severe depression, some stimulation of respiration may result. The greater part of this effect is probably a reflex stimulation from the pain caused by the irritating subcutaneous injection of camphor.

Circulation. The effects of camphor on the heart are inconstant, unpredictable and inconsequential. The literature on the cardiovascular actions of camphor, however, reveals considerable disagreement. The blood pressure may fall due to peripheral vasodilatation or it may rise slightly as a result of central vasomotor stimulation. During convulsions, the blood pressure rises; in the period of postconvulsive depression, it is low.

Absorption, Fate and Excretion. Camphor is readily absorbed from all sites of administration. It is oxidized to camphorol and excreted in the urine conjugated with glycuronic acid.

Camphor Poisoning. The ingestion of camphor moth balls by children is a common cause of camphor poisoning. The symptoms of poisoning are headache, a feeling of warmth, confusion, excitement, restlessness, delirium and hallucinations. Stimulation ultimately results in unconsciousness and epileptiform convulsions which are followed by periods of extreme depression. On rare occasions, excitement phenomena are not seen and depression is the primary symptom. Death results from respiratory failure. Treatment is the same as for other central stimulants and is largely symptomatic (*see* strychnine poisoning, page 260).

Preparations, Doses and Routes of Administration. *Camphor,* U.S.P., B.P., is a transparent, aromatic, crystalline substance. It is relatively insoluble in water. Orally, the drug is administered in crystalline form in gelatin capsules. It is dissolved in oil, usually as a 20 per cent solution, for hypodermic administration (*Ampuls of Camphor,* N.F.). The dose by either route is 0.2 gram. Other official camphor preparations are *Camphor Water,* U.S.P., B.P. (a saturated aqueous solution containing approximately one gram in 1000 cc), used as a vehicle; *Camphor Liniment,* U.S.P., B.P. (20 per cent in oil) and *Spirit of Camphor,* U.S.P., B.P. (10 per cent in alcohol).

Therapeutic Uses. On the skin, camphor is used as a *liniment,* analgesic and antipruritic. It is taken by mouth as a *carminative.* Despite the lack of evidence of its efficacy, camphor is widely used as a *circulatory and respiratory stimulant.* It is usually injected intramuscularly as a 20 per cent solution in oil. Its local irritant action may result in some reflex stimulation of the central nervous system. It is doubtful whether the drug has any appreciable systemic action in therapeutic doses. Camphor has a slight *expectorant* action and is a component of paregoric.

CHAPTER 17

THE XANTHINES

CAFFEINE, THEOPHYLLINE AND THEOBROMINE

Source and History. Caffeine, theophylline and theobromine are drugs which are similar in chemical constitution and pharmacological action. They are found in a large number of plants widely distributed throughout the world. It is of interest to note that wherever these plants are indigenous, natives have used their aqueous extracts as beverages. The consumption of some of these beverages such as coffee, tea and cocoa is practiced all over the civilized world. *Coffee,* obtained from the seeds of *Coffea arabica,* contains caffeine. *Tea,* the leaves of *Thea sinensis,* contains caffeine and theophylline. *Cocoa,* obtained from the seeds of *Theobroma cacao,* contains theobromine.

In addition, a number of caffeine beverages, less universal in appeal, are consumed in widely scattered areas. *Maté* is the national drink in many South American countries. It contains caffeine. In the vast territory of the Sudan, natives chew the Kola nut and swallow the extractives. The Kola nut is a valued possession and is used as a basis for commercial exchange. This nut contains two per cent caffeine. Many species of the *Paullinia* plant grow in the Amazon basin, but only one of these, the *Paullinia sorbilis,* is used by the natives as a beverage. This species is unique in that it contains a large amount of caffeine. Many of the so-called "soft drinks" popular in the United States maintain their appeal not only because of their flavor but also because of their caffeine content.

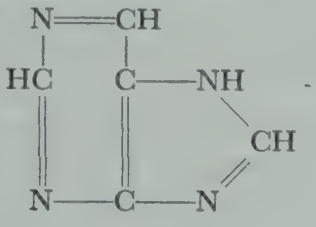
The earliest use of the xanthine beverages is lost in the obscurity of the past. However, legends telling of their discovery reveal the reason for their favor. For example, legend credits the discovery of coffee to a prior of an Arabian convent. Shepherds reported to this prior that goats which had eaten the berries of the coffee plant did not rest but gamboled and frisked about all through the night. The prior, mindful of the long nights of prayer which he had to endure, instructed the shepherds to pick the berries so that he might make a beverage from them. The success of his experiment is obvious from the popularity of coffee today, a billion pounds being consumed yearly in the United States alone.

A similar story tells of the discovery of tea by Bodhidharma who lived in the sixth century A.D. Bodhidharma, the son of a king of India and an apostle of Buddhism, traveled to China to spread his beliefs. There he lived under the open sky, mortified his flesh, tamed his passions, and subsisted on leaves. He sought sanctity by attempting to stay awake for nine years while contemplating the virtues of Buddha. After three years of this practice, he fell asleep. Upon awakening, overcome with chagrin, he cut off his eyelids so that his sin might not be repeated. A plant sprang up where his eyelids had fallen. He ate its leaves and found that he could return to his worship with renewed vigor. This plant was the tea plant.

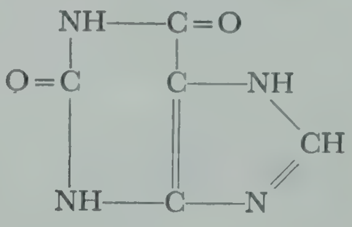
From these old tales, it can be inferred that caffeine is a stimulant, and this action is probably the basis for the popularity of the caffeine-containing beverages.

Pharmacological studies of caffeine have confirmed the stimulant property suggested by legend. The drug possesses other properties and caffeine and related compounds are valuable therapeutic agents.

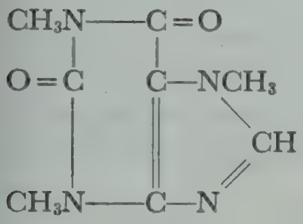
Chemistry. Caffeine, theobromine, and theophylline are methylated xanthines. They are often spoken of as "xanthine derivatives," or merely "xanthines." Xanthine itself is dioxypurine. Caffeine is 1:3:7 trimethylxanthine, theobromine 3:7 dimethylxanthine, and theophylline 1:3 dimethylxanthine. The structural formulas of purine, xanthine and the three pharmacologically important xanthine derivatives are as follows:



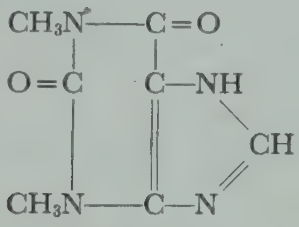
Purine



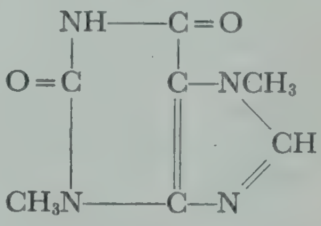
Xanthine



Caffeine



Theophylline



Theobromine

Pharmacological Actions

Caffeine, theobromine and theophylline are similar in their pharmacological properties but differ markedly in the intensity of their actions on various structures. Therefore, in the therapeutic application of these drugs for a specific effect, side-actions can be minimized and the desired response intensified by the selection of the proper xanthine. The properties of the xanthines which are utilized in therapeutics are the ability to stimulate the central nervous system, the action on the kidney to produce diuresis, the stimulating effect on cardiac muscle, and the relaxation of certain smooth muscle structures, notably the coronary arteries and bronchi. Table 12 depicts the relative potencies of the xanthines in producing these and other effects.

TABLE 12

RELATIVE PHARMACOLOGICAL POTENCIES OF THE XANTHINES

XANTHINE	C.N.S. STIMULATION	RESPIRATORY STIMULATION	DIURESIS	CORONARY DILATATION	CARDIAC STIMULATION	SKELETAL MUSCLE STIMULATION
Caffeine	1 *	1	3	3	3	2
Theophylline	2	2	1	1	1	3
Theobromine	3	3	2	2	2	1

* 1 = most potent

Central Nervous System. Caffeine is a powerful central nervous system stimulant, theophylline less so and theobromine comparatively benign in this respect. Caffeine is the xanthine usually employed clinically for its central action, but theophylline also has specific uses as a respiratory stimulant. Caffeine excites all portions of the central nervous system. The main sites of stimulation are the cortex, medulla and spinal cord. The cortex is first affected, next the medulla and the cord is stimulated only by very large amounts.

Cortex. Caffeine stimulates all portions of the cortex, but its main action is on psychic and sensory functions. It produces a more rapid and clearer flow of thought, and allays drowsiness and fatigue. After taking caffeine, one is capable of a more sustained intellectual effort and a more perfect association of ideas. There is also a keener appreciation of sensory stimuli. Motor activity is likewise increased. Typists, for example, have been found to work faster and with fewer errors. Reaction time to stimuli is appreciably diminished. There is evidence, however, that recently acquired motor skill in a task involving delicate muscular coordination and accurate timing may be affected adversely (Horst and coworkers, 1934).

The aforementioned effects of caffeine are obtained after the administration of therapeutic doses, that is, about 150 to 250 mgm for an adult. This represents the amount of caffeine ordinarily contained in a cup or two of coffee or tea. The average individual usually denies that he has experienced stimulation from ingesting a caffeine-containing beverage. The reason for this is that the type of stimulation derived from small amounts of caffeine is so physiological that one is usually unaware of it. It is only by careful tests that the true action of the drug can be demonstrated. All such investigations, starting with the classical ones of Kraepelin in 1892, have been consistent in demonstrating the stimulation of cortical centers by caffeine.

Excitation of the central nervous system is usually followed by depression. There has been considerable controversy, however, as to whether the mild physiological stimulation produced by small amounts of caffeine is followed by any depression. For example, in the researches of Horst and coworkers mentioned, a definite after-depression was observed as late as twenty-four hours after ingestion of caffeine. On the other hand, Cheney (1935) has reported no change in responsiveness which could be related to an after-depression.

Medulla. In addition to its action on the cortex, caffeine is a medullary stimulant. The medullary action, however, is manifested only when large doses are administered and is most clearly seen when the medulla is previously depressed, as, for example, by morphine. Caffeine acts on the respiratory, vasomotor and vagal centers in the medulla. When full therapeutic doses of caffeine are taken orally (150–250 mgm), there is little change in respiration. However, the same amount after parenteral administration definitely stimulates the respiratory center. The action of caffeine on the respiratory center is probably a direct one. The stimulation of the vasomotor and vagal centers can best be demonstrated in medullary perfusion experiments, because after systemic administration the peripheral effects of the drug on the circulation are such as to mask these central actions.

Effect of Large Doses. After the administration of large amounts of caffeine, the entire central nervous system is stimulated, including the spinal cord. Reflex excitability is increased. Excitation of the lower motor centers may lead to clonic convulsions, and if the dose is large the cord may be sufficiently affected so that tonic convulsions and death may result. However, such an extreme type of reaction has been observed only in experimental animals, for the toxic dose of caffeine for man is so large (over 10 grams) that no human fatalities have been reported.

Cardiovascular System. The xanthines have important actions on the circulatory system of which therapeutic use is made. Theophylline is the most active and caffeine the least. Even the action of caffeine on the circulation is quite powerful but the side-effects of this drug on the nervous system and metabolism preclude its clinical use for cardiovascular effects.

All parts of the circulatory system are affected in some way by the xanthines. In several instances, these varied actions are antagonistic. Therefore, the observation of a single function, as, for example, the effect of xanthines on blood pressure, is deceiving because the drugs may act on a variety of circulatory factors in such a way that the blood pressure may remain essentially unchanged. The observations of Starr and coworkers (1937) on the cardiovascular effects of xanthines in human subjects are presented in Table 13.

TABLE 13

CARDIOVASCULAR, RESPIRATORY AND METABOLIC EFFECTS OF CAFFEINE AND THEOPHYLLINE IN HUMAN SUBJECTS UNDER BASAL CONDITIONS †

	CAFFEINE WITH SODIUM BENZOATE * (0.5 gram intramuscularly)		THEOPHYLLINE ETHYLENE DIAMINE ** (0.48 gram intramuscularly)	
FUNCTION	Decrease %	Increase %	Decrease %	Increase %
Pulse rate	2.4		1.7	
Systolic pressure	4.0			6.8
Diastolic pressure	3.8			7.0
Cardiac output		14.8		25.8
Stroke volume		19.1		29.4
Left ventricular work per minute		9.3		35.4
Left ventricular work per beat		13.8		38.0
Heart volume	0.8		0.3	
Metabolic rate		6.9		7.8

† Data of Starr, Gamble, Margolies, Donal, Joseph and Eagle (1937).

Heart. The actions of caffeine on the heart are illustrative of the antagonistic effects which have just been mentioned. Caffeine stimulates the myocardium directly. This can readily be demonstrated in the isolated mammalian heart. The addition of xanthine to the perfusion fluid results in an increase in amplitude of excursion, rate and cardiac output. When given to an intact animal, however, in addition to stimulating the myocardium directly, the xanthines, especially caffeine, stimulate the medullary vagal nuclei. This may produce a decrease in heart rate. The ultimate effect is the net result of these two types of stimulation. Consequently, one may observe in different individuals slight bradycardia or tachycardia following the ingestion of caffeine (Horst and coworkers, 1934, 1936). After high doses of caffeine, or the injection of large amounts in experimental animals, a definite tachycardia ensues from a direct stimulation of the myocardium. Eventually this stimulation may become so great as to cause cardiac irregularities. Occasionally, arrhythmias may be encountered in persons who use caffeine beverages to excess.

The direct myocardial action of the xanthines causes an increase in cardiac output. The increase is not due to a more rapid cardiac rate for it may occur independently of tachycardia. Rather, it results either from a greater stroke volume or an accelerated venous return.

Blood Vessels. Caffeine tends to constrict blood vessels by stimulation of the medullary vasomotor center, and to dilate them by a direct effect on vascular musculature. Here again, the central and peripheral actions are antagonistic.

After therapeutic doses, the peripheral vasodilator action predominates. Oncometer studies in experimental animals show that there is a definite increase in organ volume following the administration of a xanthine. Vasodilatation, coupled with an augmented cardiac output, results in an increased blood flow.

Coronary Circulation. The coronary vessels are also relaxed by the xanthines. This has been demonstrated experimentally both in intact unanesthetized animals and in anesthetized animals when an increase in coronary circulation sometimes as great as 100 per cent follows xanthine medication (Essex and coworkers, 1940; Boyer and coworkers, 1939). The claim has been made that the xanthines also facilitate the establishment of collateral coronary circulation in dogs with experimental myocardial infarction (Fowler, Hurevitz and Smith, 1935). Wiggers and Green (1936) and Gold and coworkers (1937), however, have been unable to confirm this finding.

Experiments designed to elucidate the action of the xanthines on coronary blood flow are of considerable practical importance for the drugs are extensively employed in patients with disease of the coronary artery. The question is actively debated as to whether the vasodilator effect of the xanthines on the coronary arteries of man is sufficiently great to be of therapeutic value. Unfortunately, one cannot use a direct experimental approach to the solution of this problem. Rather a decision concerning the efficacy of the drugs must rest on clinical data obtained from studies of the relief afforded by xanthines to patients with impaired coronary circulation. The results of such investigations are discussed under the clinical uses of the xanthines.

Blood Pressure. It should be obvious from the foregoing discussion that the effect of xanthines on the systemic blood pressure is unpredictable. The actions which would favor an increase in blood pressure are central vasomotor and direct myocardial stimulation. Conversely, the factors favoring a decrease in blood pressure are central vagal stimulation and peripheral vasodilatation. The end-result on blood pressure of these opposing actions is not striking but it usually consists of a slight rise, seldom amounting to more than 10 mm of mercury. The slight elevation in pressure is mainly the result of the increase in cardiac output and occurs despite peripheral vasodilatation. The latter, in turn, masks any effect of central vasomotor stimulation. The combination of vasodilatation and enhanced cardiac output produces a more rapid blood flow and a more efficient circulation.

An unusual effect of the xanthines on blood pressure is the sharp but transitory fall which follows their rapid intravenous injection. The exact mechanism of this fall is unknown. It has been suggested that a high concentration of drug depresses the myocardium, but it is more likely that the fall in blood pressure is due to a precipitation of the xanthine alkaloids in the blood. The compounds are feebly basic and the acid salts which they form may easily be thrown out of solution when they encounter the alkaline reaction of the blood. When xanthine salts are administered intravenously, the rate of injection should be very slow.

Smooth Muscle. The xanthines act on smooth muscles other than those of blood vessels. Walters and coworkers (1937) have shown that theophylline ethylenediamine is effective in overcoming the spasm of the *biliary tract* produced in human beings by the injection of morphine, dilaudid or codeine (Figure 59). On the basis of this observation, the xanthines deserve a trial in the treatment of biliary colic. The action of the xanthines on the motor activity of the remainder of the *gastro-intestinal tract* is unimportant. Dilute solutions increase and high concentrations depress the tone and amplitude of contractions of isolated intestinal strips. In the body, however, therapeutic doses of xanthines have no significant effect on gastro-intestinal activity.

The smooth muscles of the *bronchi* are also relaxed by the xanthines especially if constricted experimentally by histamine or clinically in asthma. Greene and coworkers (1937) have obtained relief in cases of bronchial asthma following the administration of theophylline. A definite increase in vital capacity is associated with the symptomatic relief afforded by the drug. These investigators reported that asthmatics refractory to epinephrine may respond favorably to theophylline. The dyspnea of cardiac failure also reacts favorably to xanthine administration. In this condition, however, relief is due not so much to bronchial dilatation as to an improved cerebral circulation with a resulting decrease in intrathecal and venous pressures. The effect of theophylline on Cheyne-Stokes respiration associated with cardiovascular disease is shown in Figure 24.

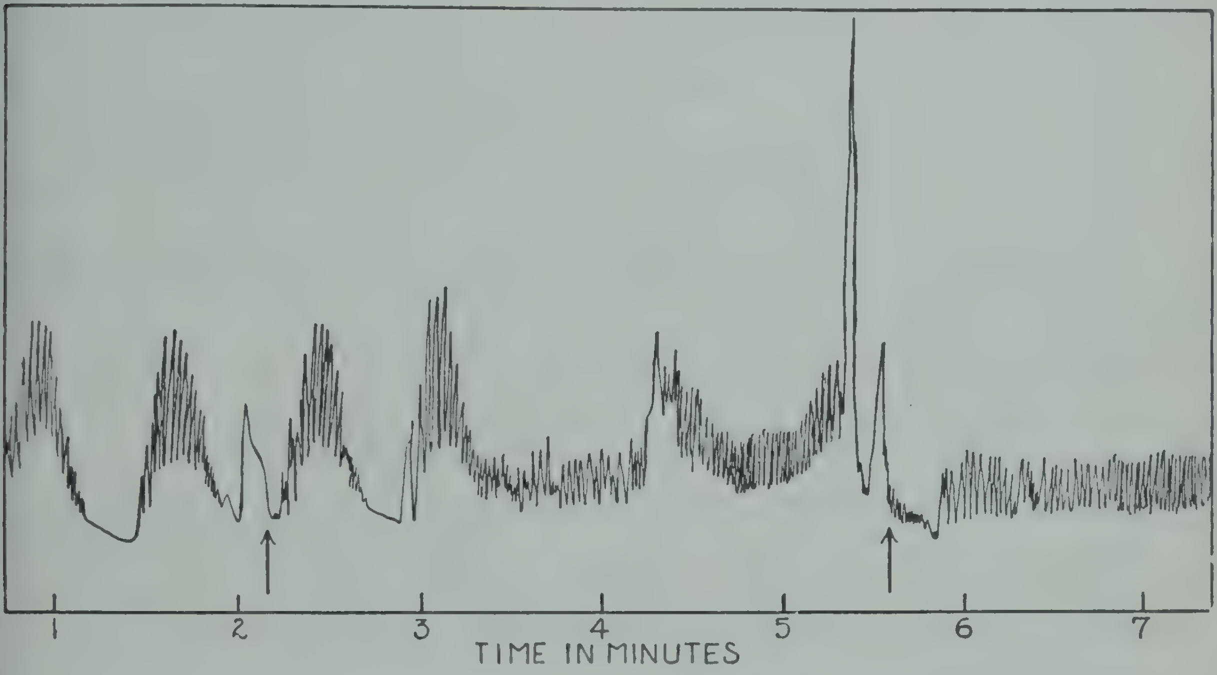

Figure 24. *The effect of theophylline on Cheyne-Stokes respiration.*

Plethysmographic tracing of respiratory movements in a patient with Cheyne-Stokes breathing associated with cardiovascular disease. Theophylline ethylene diamine, 0.48 gram, was injected intravenously in 30 cc of isotonic sodium chloride solution over the period indicated between the arrows. Note the rapid cessation of periodic breathing and the return of normal respiration. (After Greene and Heeren, 1936. Courtesy of the *Waverly Press.*)

Voluntary Muscle. The effect of the xanthines on voluntary muscle is disputed. Although it is agreed that the ingestion of caffeine allays fatigue, there is no unanimity of opinion as to the mechanism of this action. Some investigators believe that it is due to a direct action of the drug on muscles, whereas others claim that central stimulation masks the recognition of fatigue. There are many experimental observations which suggest that the xanthines have a direct action on skeletal muscles. For example, certain species of frogs show marked rigor following the injection of these drugs. The rigor is peripheral rather than central in origin for it is not influenced by nerve section or curare. A definite rigor can be produced in mammalian muscle by injecting a xanthine directly into the muscle. Accompanying this action there is an increase in oxygen consumption and heat production of the muscle. Furthermore, an isolated nerve-muscle preparation is less susceptible to fatigue if a low concentration of a xanthine is present in the bath fluid.

Despite the evidence indicating a peripheral action on skeletal muscle, there is good reason to believe that the central effects of the xanthines account for the increased capacity for muscular work demonstrable in man. The strongest argument in support of this view is the observation that theobromine has the greatest peripheral effect on muscle and yet is relatively ineffective in increasing the capacity for muscular work. Caffeine, on the other hand, is most effective in increasing muscular performance and also has the greatest capacity for stimulating the central nervous system. One may conclude, therefore, that although the xanthines stimulate skeletal muscles under experimental conditions to the extent of rigor, it is the stimulation of the central nervous system which prevents the sense of fatigue and is responsible for the increased capacity for muscular work which follows caffeine consumption.

Diuretic Action. All of the xanthines increase the flow of urine. Theophylline is the most powerful xanthine diuretic but its action is short in duration. Theobromine is slightly less active but its effect is more sustained. Caffeine is the least powerful. A detailed analysis of the mechanism of the diuretic action is given on page 636. The therapeutic uses of the xanthine diuretics are discussed on page 644.

Metabolism. The xanthines, especially caffeine, slightly increase the basal metabolic rate. Numerous investigators have reported that after the ingestion of 0.5 gram of caffeine the basal metabolic rate may increase an average of 10 per cent and occasionally 25 per cent. The maximum change occurs from one to three hours after the administration of the drug. Statistical studies have revealed that the basal metabolic rate of habitual coffee drinkers is slightly higher than normal.

Tolerance. An appreciable degree of tolerance may develop to certain effects of the xanthines, especially the diuretic and vasodilator actions. Cross-tolerance between the members of the group also occurs. No tolerance develops to the central stimulation. Habituation is discussed under caffeine beverages.

Toxicology. The fatal oral dose of caffeine for adults is estimated to be about 10 grams, but no deaths have been reported. Untoward reactions, however, may be observed following the ingestion of one or more grams of caffeine. These are mainly referable to the central nervous and circulatory systems. Insomnia, restlessness and excitement are the earliest symptoms, and may progress to a mild delirium. Sensory disturbances, such as ringing in the ears and flashes of light, are common. The muscles become tense and tremulous. Tachycardia and extrasystoles are frequent and the respiration is quickened. The diuretic action of the drug may be prominent.

If a fatal dose of caffeine is given to animals, central nervous system stimulation proceeds to the convulsive stage. Early in the poisoning, the convulsions are epileptiform in nature; but, as the action of the drug on the spinal cord becomes manifest, they may be replaced by strychnine-like tonic convulsions. Death results from respiratory failure.

The central symptoms of caffeine poisoning may be readily controlled by the administration of depressants of the central nervous system. The short-acting barbiturates are effective and convenient.

Absorption, Fate and Excretion. The xanthines are readily absorbed after oral or parenteral administration. In the case of caffeine, a small portion of the drug is excreted in the urine unchanged or partially demethylated. About 80 per cent of the drug is broken down in the body to urea and not to uric acid, as might be expected. Theobromine and theophylline share the same fate as caffeine except that a slightly larger portion of these drugs may appear unchanged in the urine.

Preparations and Routes of Administration. The xanthines are weakly basic alkaloids. They are usually dispensed in the form of soluble double salts which they form with a number of compounds. For oral administration, either the free base or the double salts may be used. For parenteral administration, however, it is necessary to employ one of the injectable salts.

Caffeine. Caffeine, U.S.P., B.P., is also known as *theine.* It consists of white glistening crystals soluble in water to the extent of 1:46. Two widely employed soluble salts are *Citrated Caffeine,* U.S.P., a mixture of caffeine and citric acid in equal amounts by weight, and *Caffeine with Sodium Benzoate,* U.S.P., B.P., a mixture of equal parts of caffeine and sodium benzoate. For hypodermic administration, the benzoate salt should be used. Both are white water-soluble powders having a slightly bitter taste.

Theobromine. The U.S.P. and B.P. preparation is *Theobromine with Sodium Salicylate,* also known as *diuretin.* It is a white water-soluble powder of sweetish alkaline taste which contains approximately 46 per cent theobromine. In addition, three commonly employed theobromine preparations are included in the N.N.R. They are the free base, *Theobromine,* N.N.R., a white, crystalline, bitter powder slightly soluble in water; *Theobromine Sodium-Acetate,* N.N.R., a white, crystalline, water-soluble bitter powder, which contains not less than 63 per cent theobromine; *Theocalcin,* N.N.R., a mixture of calcium theobromine (44 per cent) and calcium salicylate, which consists of a white amorphous powder having a saline taste and only partly soluble in water. Theobromine preparations may be given only by the oral route.

Theophylline. The commonly employed theophylline preparations are as follows: *Theophylline,* U.S.P., B.P., a white, crystalline, bitter powder soluble 1:120 in water; *Theophylline with Ethylene Diamine* (Aminophylline), U.S.P., a combination containing 70 per cent of theophylline and consisting of white or slightly yellow granules possessing a slight ammoniacal odor and bitter taste, soluble 1:5 in water; *Theophylline with Sodium Acetate,* U.S.P., B.P., which contains 60 per cent theophylline and consists of a white, crystalline, bitter powder soluble 1:35 in water. Theophylline with ethylene diamine is the preparation employed for parenteral administration.

Choice of Preparation. The large number of available xanthines often leads to confusion as to the best preparation to employ. The compounds of caffeine are usually utilized only as central stimulants. Theobromine and theophylline are often used interchangeably for their actions on the coronary circulation and kidney. The choice of preparation is also influenced by the side-actions produced and the cost of medication.

An important side-action is the local effect of xanthines on the gastric mucosa. All preparations are irritating and in therapeutic doses are likely to cause gastric discomfort, nausea and vomiting. Often it is impossible to give the desired amount, and in many instances it is the limit of gastric tolerance which finally determines the dose employed. It is best to give the xanthine drugs after meals in order to reduce the factor of gastric irritation.

Although claims have been made that some salts are less irritating than others to the gastro-intestinal tract, this difference is not sufficiently noticeable to make any one preparation outstanding. The xanthine salts vary considerably in cost (Brown and Riseman, 1937) and this may in part determine the choice of drug when chronic medication is necessary.

Therapeutic Uses. The xanthines are extensively employed as *diuretics.* A detailed discussion of their use in edema appears on page 644.

Another wide use of the xanthines, particularly theophylline and theobromine preparations, is in the treatment of patients with insufficiency of the coronary circulation, as in *angina pectoris.* The vasodilator effect of the xanthines on the coronary arteries has been discussed. Clinical observations have led to the belief that chronic medication with xanthines results in a decrease in the number and severity of anginal attacks. The efficacy of such therapy, however, has been questioned especially by Evans and Hoyle (1933), Gold, Kwit and Otto (1937) and Masters and coworkers (1939). From carefully controlled clinical studies, Gold and Masters and their respective associates came to the conclusion that patients were unable to detect any difference between the effects of xanthines and suitably disguised placebos. On the basis of such findings, the Council on Pharmacy and Chemistry (1937) decided not to accept for inclusion in N.N.R. any xanthine preparation for which claims of therapeutic value in coronary artery disease are made. However, Brown and Riseman (1937) have taken exception to these conclusions. These investigators employed an exercise tolerance test and demonstrated that, although a patient could not distinguish between a xanthine and a placebo on the basis of a subjective analysis of symptoms, he could withstand more physical exertion without experiencing anginal pain after the administration of a xanthine than he could without such medication or after taking a disguised placebo.

Therefore, the status of the xanthines in the treatment of coronary artery disease still remains controversial. When used, the xanthine drugs are given three times daily during meals. The salts may be better tolerated than the free bases. The average single dose of the theophylline compounds is approximately 0.25 gram, of the theobromine salts, 0.6 gram. No statement can be made as to which xanthine salt is most effective. Many physicians give medication for only four days of each week in order to avoid tolerance. It is also a common practice to alternate between a theobromine and a theophylline salt. If gastric disturbance becomes severe, the dosage must be reduced or another preparation tried.

The *direct myocardial stimulation* produced by the xanthines has relatively little therapeutic application. The drugs are not suitable for chronic medication as cardiac stimulants, and more effective agents are available for the treatment of chronic cardiac insufficiency. In *acute circulatory failure,* the xanthines may be of some value, but in the majority of cases the failure is of peripheral rather than cardiac origin. If there is a myocardial element in the circulatory collapse, the parenteral injection of caffeine or theophylline is sometimes beneficial. In patients with *paroxysmal nocturnal dyspnea* due to left ventricular insufficiency, xanthine medication brings relief. In addition to causing cardiac stimulation, the drug relaxes the bronchial musculature, which may further alleviate dyspnea if there is a superimposed factor of bronchospasm. Also, venous and intrathecal pressures are lowered. Theophylline with ethylene diamine is the preparation of choice. It is used in the parenteral dose of 0.25 to 0.50 gram and it may be given intravenously in an emergency.

The *central actions* of caffeine are particularly useful in treating cases of *poisoning by the central depressants.* In morphine poisoning, the direct effect of caffeine on the medulla is of particular value. The drug is given by intramuscular injection as the sodium benzoate salt or by enema in the form of black coffee. The dose of caffeine with sodium benzoate is 0.5 to 1.0 gram.

The xanthines have been used in the treatment of *peripheral vascular disease,* but the results have been disappointing. Scupham (1934) observed some symptomatic relief in cases of early thromboangiitis obliterans, but in general his results were not encouraging. McGovern, McDevitt and Wright (1936) found the xanthines too unreliable and feeble as vasodilators to be of any value in the treatment of peripheral vascular disorders.

In the treatment of *bronchial asthma,* theophylline with ethylene diamine has proved of definite value. The drug is of special benefit in patients refractory to epinephrine. Herrmann and Aynesworth (1937) have reported favorable results in a series of cases of status asthmaticus. The effective dose of 0.25 to 0.50 gram is dissolved in 10 cc of physiological sodium chloride solution and is given slowly intravenously. Favorable responses in bronchial asthma have also been reported following the intramuscular injection of the drug. Oral therapy is usually ineffective in severe or acute attacks, but is useful in mild or chronic cases.

Caffeine has been extensively employed, especially in combination with analgesics and hypnotics, in the treatment of *headache* and *migraine.* The mechanism of action of caffeine in headache may possibly be related to the changes which the drug produces in the cerebral circulation. It is difficult to judge the benefit obtained from caffeine, especially when it is used with other drugs.

XANTHINE BEVERAGES

The most popular of the xanthine beverages are coffee, tea and cocoa. Coffee and tea contain caffeine, whereas cocoa contains theobromine. The caffeine content of tea leaves is higher than that of coffee beans, but the beverages as finally prepared are approximately equal in their alkaloidal content inasmuch as proportionately more coffee is employed. The average cup of coffee contains between 100 and 150 mgm of caffeine, approximately a therapeutic dose. Naturally, the daily ingestion of this amount of a potent alkaloid is bound to exert some pharmacological action. In addition to alkaloids, coffee contains certain oils and tea has an appreciable amount of tannin.

There is little doubt that the xanthine beverages are often consumed for their stimulating action. This probably forms the main basis for their popularity, although most persons are unaware of any stimulation. The xanthine beverages present a medical problem in that they are a dietary source of a stimulant of the central nervous system. Often the physician is faced with the question whether to deny caffeine-containing beverages to patients.

The degree to which an individual is stimulated by a given amount of caffeine varies. It probably is related to what may be termed "individual temperament." For example, if some persons ingest caffeine beverages in the evening, insomnia is almost certain to result. Others boast of their ability to drink coffee and "sleep like a log." Therefore, the degree of action of caffeine is largely influenced by the base line of nervous system irritability. Some individuals are stimulated to a degree that precludes the possibility of adequate relaxation after xanthine beverages. In fact, there are rare persons who are so sensitive to caffeine that even a single cup of coffee will cause a response bordering on the toxic.

Children are more susceptible than adults to xanthine stimulation. Their normal reflex excitability is generally high. What is more, the ingestion of caffeine beverages may interfere with the consumption of necessary foodstuffs. For these reasons, tea and coffee should be excluded from the diet of children. Cocoa, however, which contains theobromine rather than caffeine, may be allowed especially if it is made with milk.

There are certain pathological conditions in which it has been suggested that xanthine beverages be denied to patients. The fact that the xanthines are closely related in structure to uric acid has led to the belief that tea and coffee should be excluded from the diet of patients suffering from gout. However, the methylated xanthines are not excreted as uric acid but rather are broken down to urea, and careful studies have shown that they do not appreciably increase the uric acid content of the urine. Therefore it is doubtful whether on this basis the xanthines could have an adverse effect on podagric individuals.

Often xanthine beverages are denied to individuals with hypertension because of the action of caffeine on the cardiovascular and nervous systems. Obviously in a disease in which sedation is an important factor, stimulation by a xanthine is not to be desired. However, most authorities take the attitude that the complete denial of coffee to an individual who enjoys it is apt to be more disturbing than any stimulation he may receive from the beverage. Again, many patients with hypertension experience neither an increase in blood pressure nor nervousness from xanthine beverages. Indeed, theobromine is frequently prescribed for its renal and perhaps coronary actions in such patients. Xanthine beverages accomplish the same end and in addition may relieve the headache so common in this syndrome. Therefore, coffee and tea are not denied, but their intake may have to be controlled.

Overindulgence in xanthine beverages may lead to a condition which might be considered one of chronic poisoning. Central nervous stimulation results in restlessness and disturbed sleep. Myocardial stimulation is reflected in cardiac irregularities, especially premature systoles, palpitation and tachycardia. The essential oils of coffee may cause some gastro-intestinal irritation, and diarrhea is a common symptom. The high tannin content of tea, on the other hand, is apt to cause constipation.

There is no doubt that a certain degree of psychic dependence (*i.e.*, habituation) develops to the xanthine beverages. This is probably true even of those individuals who do not partake to excess. However, the morning cup of coffee is so much a part of the American dietary that one seldom looks upon its consumption as a drug habit, and there is no evidence that the practice is in any way harmful. The feeling of well-being and increased performance which it affords, although possibly obtained at the expense of decreased efficiency later in the day, is one which few individuals would care to give up

SECTION IV

LOCAL ANESTHETICS

CHAPTER 18

COCAINE; PROCAINE AND OTHER SYNTHETIC LOCAL ANESTHETICS

THE GENERAL PHARMACOLOGY OF THE LOCAL ANESTHETICS

The local anesthetic drugs are capable of blocking nerve conduction when applied locally to nerve tissue in effective concentration. They exert this effect on any portion of the nervous system and on every type of nerve fiber. For example, the application of a local anesthetic to the motor cortex blocks impulse transmission from that area, and at the other extreme the drug's application to afferent nerve endings prevents the reception of stimuli and transmission of sensory impulses. A local anesthetic in contact with a mixed nerve trunk causes motor and sensory paralysis of the area innervated. The conduction of nerve impulses in the spinal cord may be blocked so completely that cord transection is functionally simulated. The great practical value of the local anesthetic drugs is due to the fact that their action is reversible and is followed by complete recovery of nerve function with no evidence of structural damage to nerve fibers or cells. By the proper use of local anesthetics one can produce sensory and motor paralysis in selected discrete areas with no other effect than the desired local one.

History. The first local anesthetic discovered was cocaine. The alkaloid was isolated in 1860 by Niemann, a pupil of Wöhler. Wöhler noted that cocaine was bitter to the taste and had a peculiar effect on the nerves of the tongue, making it numb and almost devoid of sensation. Von Anrep in 1879 studied the pharmacological actions of cocaine and found that after subcutaneous injection the skin overlying the injected area became insensitive to the prick of a pin. He recommended that this compound might be useful clinically as a local anesthetic. His suggestion was not acted upon, however, and credit for the discovery of local anesthesia is usually ascribed to Sigmund Freud and Karl Köller. A popular story relates that these two investigators were searching for a morphine substitute, and in the course of their studies on cocaine Köller accidentally got some of the drug in his eye and fortunately noted the resulting anesthesia. This story is denied by both principals. The following interesting account of the discovery of local anesthesia appears in Freud's autobiography (1935):

> “In the autumn of 1886 I settled down in Vienna as a physician, and married the girl who had been waiting for me in a distant city for more than four years. I may here go back a little and explain how it was the fault of my fiancée that I was not already famous at that early age. A side interest, though it was a deep one, had led me in 1884 to obtain from Merck some of what was then the little-known alkaloid cocaine and to study its physiological action. While I was in the middle of this work, an opportunity arose for making a journey to visit my fiancée, from whom I had been parted for two years. I hastily wound up my investigations on cocaine and contented myself in my book on the subject with prophesying that further uses for it would soon be found. I suggested, however, to my friend Königstein, the ophthalmologist, that he should investigate the question of how far the anesthetizing properties of cocaine were applicable in diseases of the eye. When I returned from my holiday I found that not he, but another of my friends, Carl Köller (now in New York), whom I had also spoken to about cocaine, had made the decisive experiments upon animals' eyes and had demonstrated them at the Ophthalmological Congress at Heidelberg. Köller is therefore rightly regarded as the discoverer of local anes-

thesia by cocaine, which has become so important in minor surgery; but I bore my fiancée no grudge for her interruption of my work."

The acceptance of cocaine as a local anesthetic was immediate, and in this way the history of local anesthesia differs sharply from that of general anesthesia. Other investigators rapidly extended Köller's initial observation. Within a short time, Hall (1884) introduced local anesthesia into dentistry, and Halsted (1885) by demonstrating that cocaine could block transmission in nerve trunks laid the foundation for block anesthesia in surgery. Corning (1885) produced spinal anesthesia in dogs, but several years passed before this technic was employed in clinical surgery.

Chemical search for cocaine substitutes started in 1892 with the work of Einhorn, and in 1905 this investigator synthesized procaine, which today is more extensively employed than any other local anesthetic. Chemical investigation still continues, however, because no available local anesthetic is free of undesirable properties. As a result an unnecessarily large number of compounds are marketed for clinical use. Most of these differ little in therapeutic efficiency, and few have distinctive features to recommend their use.

Properties Desirable in Local Anesthetics. A good local anesthetic should combine several desirable properties. Obviously it should not be irritating upon local application, and must produce anesthesia without causing damage to nerve structure. Most of the local anesthetics used today fulfill these requirements. The systemic toxicity of a local anesthetic should be low because the compounds are absorbed from their site of local application. The concentration in which a local anesthetic is effective is an important factor to consider in judging the safety of the drug. For example, if the systemic toxicity of two compounds is identical but one requires a higher concentration for local anesthesia, they cannot be considered equally safe in their clinical use. It is clear that the lower the effective anesthetic concentration and the higher the fatal dose, the greater is the margin of safety. In the discussion of barbiturates, it was pointed out that in this series of drugs the toxic and therapeutic doses are proportional and closely parallel each other throughout the series. This does not hold true for the local anesthetics. Compounds equally effective may differ markedly in their toxicity, a fact indicating that the two properties are quite independent. This dissociation of toxicity and potency affords a great stimulus in the search for new, more effective and safer anesthetic agents.

The duration of anesthetic action is another important factor in determining the desirability of a local anesthetic. It must be sufficiently long to allow ample time for the performance of the contemplated surgical procedure. The time required for the onset of anesthesia is likewise important, and should be as short as possible. The ideal local anesthetic also is one which is effective regardless of the locus of administration. It should be active when injected or when applied locally to mucous membranes.

There are excellent laboratory procedures available for testing the factors discussed, and the choice of suitable agents for clinical trial is largely determined by the results obtained from such tests. The laboratory data for several of the more commonly used local anesthetics are presented in Table 15.

General Properties of Local Anesthetic Drugs

The local anesthetics as a group have many actions in common, and before discussing the pharmacology of the individual members these general properties will be considered.

Mechanism of Action. Little is known of the mechanism of action of the local anesthetics. It has been postulated that they act in the same basic manner as general anesthetics, the main difference being that a higher concentration of local anesthetic is necessary. According to this view, local anesthetics are not active after systemic administration because death occurs from medullary depression before the higher centers are anesthetized. There is little evidence in support of this theory.

Despite the paucity of information concerning the mechanism of local anesthesia, it is known that certain nerve fibers are more susceptible than others to the action of this group of drugs. Thus it has been found that in a mixed nerve the sensory fibers are blocked earlier than the motor. In fact, when the proper concentration of anesthetic is applied to a nerve, it is possible to block completely the sensory fibers without abolishing the transmission of motor impulses. Also, it has been established that there is a definite order in which the fibers in a sensory nerve are affected by local anesthetics. The sensation of pain is the first modality to disappear and it is followed in order by the sensations of cold, warmth and touch. Various theories have been presented to explain this difference in susceptibility. For a long time it was thought that the phenomenon was due to a difference in the chemical constitution of the fibers. Gasser and Erlanger (1929), however, were impressed with the fact that when pressure is applied to a mixed nerve the resulting anesthesia of the motor and sensory fibers appears in a sequence opposite to that observed after block by anesthetic drugs, namely, the motor fibers are affected before the sensory. They demonstrated by the use of the cathode ray oscillograph that fiber size is the main factor in determining the relative sensitivity to pressure and to chemical anesthesia. After cocaine is applied to a mixed nerve, the gamma waves (from small cutaneous afferent fibers) are the first and the alpha waves (from large fibers) the last to disappear. Inasmuch as cocaine probably acts by chemical combination with the nerve protoplasm, it is logical that the smaller fibers which present the greatest surface per unit of volume are the first to be anesthetized. This concept receives support from the observation that if a local anesthetic is applied to the vagus nerve, the smaller efferent cardioinhibitory fibers are blocked before the larger fibers which carry afferent respiratory impulses.

Action on the Myoneural Junction and Ganglionic Synapse. The actions of local anesthetics are not confined to nerve trunks and fibers but apparently affect synaptic transmission as well. Harvey (1939) has studied the effects of procaine on synaptic transmission in the light of the newer knowledge of the chemical mediation of the nerve impulse (page 323). He prepared decerebrate cats for close intra-arterial injection of the tibialis anterior muscle and observed that the intra-arterial injection of as little as 0.2 mgm of procaine reduced the tension of muscle twitches evoked by maximal motor nerve volleys delivered at 10-second intervals. The response to tetanic stimulation was also impeded, but the muscle responded normally to direct electrical stimulation. That the effect of the local anesthetic was not solely on the motor nerve endings was shown by the fact that the response of the muscle to injected acetylcholine was blocked. The actions of procaine and physostigmine were antagonistic; of procaine and curare, additive. There was no stimulatory phase to the action of procaine on muscle and in every way it could be likened to that of curare.

Similarly if procaine was added to the fluid perfusing a ganglion, ganglionic transmission was impeded. Preganglionic stimuli failed to elicit postganglionic discharges and the ganglion cells became insensitive to stimulation by acetylcholine. That procaine, however, had a marked effect on synaptic endings of preganglionic fibers as well as on ganglion cells was shown by the fact that the production of acetylcholine in response to preganglionic stimulation was diminished. In this respect the actions of procaine and curare differ.

Potentiation by Alkali. The local anesthetics are generally marketed in the form of their water-soluble acid salts, usually the hydrochlorides. There is evidence to show, however, that it is the free base which acts on nerve tissue. In their basic form, the local anesthetics are lipid-soluble. In fact, to a certain extent they obey the Meyer-Overton law (page 32). It is highly probable that the free base is liberated in the tissues by the slightly alkaline body fluids. Most of the local anesthetics are tertiary amines, and the reaction which takes place in the tissues may be simply illustrated as follows:

$$\underset{\text{Acid Salt}}{R\vdots N\cdot HCl} + NaHCO_3 \longrightarrow \underset{\text{Free Base}}{R\vdots N} + NaCl + H_2CO_3$$

It is possible to demonstrate that the addition of alkali to anesthetic solutions increases, to some extent, their anesthetic potency. After alkalinization, however, the solutions become turbid, and the free base may separate out. As a practical therapeutic procedure, therefore, alkalinization of anesthetic solutions is seldom employed. Rather one relies on the ability of tissue fluids to liberate the active base. In extreme conditions, when the anesthetics encounter an acid reaction in tissues, as in acutely infected areas, it is difficult to produce local anesthesia.

A certain amount of the free base is liberated by the spontaneous hydrolysis of a local anesthetic salt in aqueous solution. The extent of hydrolysis is influenced by the strength of both the acid and base portions of the molecule. When the local anesthetic is present as the salt of a strong acid, *i.e.,* a hydrochloride, spontaneous hydrolysis is at a minimum. The salts of weak acids, however, hydrolyze more readily. In an attempt to take practical advantage of this physical property, boric acid salts of local anesthetics have been marketed. Presumably the liberation of the free base is facilitated. Although an increased efficiency can be demonstrated in the laboratory, it is not of sufficient magnitude to be of clinical significance. Again, there is evidence that the degree of basicity of the free anesthetic alkaloid influences the rate of spontaneous hydrolysis of its salts and has a marked effect on anesthetic potency. Thus the less basic alkaloids are more active inasmuch as their salts hydrolyze more readily to yield the active free base.

Potentiation by Epinephrine. The duration of action of local anesthetics is proportional to the time during which they are in actual contact with nervous tissue. Consequently procedures which localize the drug at the nerve greatly prolong the period of anesthesia. Cocaine itself constricts blood vessels and therefore prevents its own absorption. For this reason, the duration of cocaine anesthesia is greater than that of most anesthetics which do not cause vasoconstriction. Braun in 1903 demonstrated that the addition of epinephrine to local anesthetic solutions greatly prolongs and intensifies their action. In clinical practice, therefore, the injection of a local anesthetic is usually accompanied by epinephrine or one of its suitable synthetic congeners. A concentration of 1:25,000 to 1:50,000 of epinephrine hydrochloride is sufficient for this purpose. The epinephrine performs a dual service. By decreasing the rate of absorption epinephrine not only localizes the anesthetic agent at the desired site but also allows the rate at which the anesthetic is destroyed in the body to keep pace with the rate at which it enters the circulation. Thus a toxic concentration is not reached.

Fate of Local Anesthetics. All the local anesthetics are destroyed by the liver. The rate at which they are destroyed, however, varies greatly and this is a major factor in determining the safety of a particular anesthetic agent. In practical use, the toxicity of a local anesthetic depends upon the ratio between the rate of absorption and the rate of destruction. As has already been stated, the rate of absorption of all the anesthetic agents can be reduced nearly to a common base line by the incorporation of epinephrine in the anesthetic solution. With respect to rate of destruction, Eggleston and Hatcher (1919) showed that the local anesthetics can be divided into two groups, those rapidly and those slowly detoxified.

One minimal lethal dose of a member of the first group can be detoxified by the body in 20 minutes, whereas 60 minutes are required for the slowly detoxified local anesthetics. The speed with which the liver can detoxify different local anesthetics is one of the chief reasons for their varying toxicities.

There is abundant proof that the liver is the site of destruction of the local anesthetics. These drugs lose their toxicity after perfusion through the liver, probably as the result of hydrolysis. Also animals with experimentally produced liver damage are much more susceptible to the toxic actions of local anesthetics. This suggests that extensive use of a local anesthetic should perhaps be avoided in patients with severe liver damage. Those anesthetic agents which are slowly destroyed by the liver are partially eliminated in the urine but only a small fraction is normally excreted by the kidney.

Toxicity of Local Anesthetics. *Central Nervous System.* There is a wide variation in the lethal doses of the various local anesthetics. The degree of toxicity does not always parallel the degree of anesthetic activity, and there apparently need be no obligatory relationship between the two. On the other hand, it is highly significant that all the local anesthetics produce the same type of symptoms when given in toxic amounts. These symptoms, mainly referable to the central nervous system, result from central stimulation and consist chiefly of restlessness and tremors which proceed to clonic convulsions. Stimulation is followed by depression and death is usually due to respiratory failure. In fact, it is possible to protect animals from two to three times the minimal lethal dose of a local anesthetic by the use of artificial respiration (Tatum, Atkinson and Collins, 1925). Attempts have therefore been made to use respiratory stimulants as antidotes against the toxic effects of local anesthetics. Such procedures have proved ineffective, however, for the reason that the local anesthetics in themselves are central nervous system stimulants, and the eventual depression of the respiratory center which they produce is that which characteristically follows excessive stimulation.

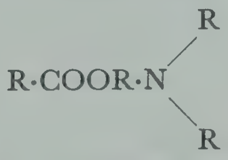
Tatum, Atkinson, and Collins (1925) pointed out that the logical drugs to use in the prevention and treatment of poisoning by local anesthetics are the hypnotics. Of this group, they found that the barbiturates are the most valuable. Not only are the barbiturates effective in arresting convulsions resulting from an overdose of local anesthetic but if given prophylactically the minimal lethal dose of the local anesthetic is increased three or four times. The practical importance of these observations is mentioned under the clinical use of the local anesthetics. Different species of animals vary in susceptibility to central stimulation by local anesthetics, and seemingly this is related to the degree of development of the central nervous system. Thus the higher forms, such as monkey and man, are much more sensitive to the toxic action of these drugs. Tatum and Collins (1926) showed that the barbiturates afford the higher species relatively more protection.

Whereas all the local anesthetics stimulate the central nervous system, cocaine is unique in having a powerful action on the cortex. This property of cocaine and its ability to produce addiction will be discussed later. The synthetic local anesthetics, in contrast, are less stimulating to the higher cerebral centers and are incapable of causing addiction.

Cardiovascular Actions. In addition to their toxic effect on the central nervous system the local anesthetics may act adversely on the circulatory system. Cocaine has the most pronounced action and the synthetic local anesthetics are variable in this respect. Upon intravenous injection, some may produce a slight rise in blood pressure; others, a fall. These slight alterations in blood pressure are usually unimportant. On rare occasions, however, the administration of relatively small amounts of a local anesthetic may result in sudden cardiovascular collapse and death. This untoward reaction must be classified as an idiosyncrasy for it occurs rarely and bears no relation to dosage. Some of the toxic manifestations following the administration of local anesthetic solutions are due to sensitivity to epinephrine. Reactions to epinephrine are not uncommon.

A unique action of local anesthetics, particularly procaine, is their ability to reduce the irritability of heart muscle to noxious stimuli of an electrical or chemical nature. Mautz (1936) showed that the local application of anesthetics to the ventricular muscle raised the threshold for the induction of ventricular extrasystoles by electrical stimulation. Of even greater interest is the fact that the intravenous administration of procaine protects animals anesthetized by cyclopropane from the ventricular fibrillation which can be induced by epinephrine (Burstein and Marangoni, 1940) and that the intracardiac injection of procaine can stop fibrillation that has already become established (Marangoni, Burstein and Rovenstine, 1940). The mechanism of this action has not been determined.

Chemistry of Local Anesthetics: Relationship Between Constitution and Action. The pharmacological activity of most synthetic local anesthetics apparently resides in a certain basic structure. Inspection of the structural formulas of the individual anesthetics reveals that they are tertiary amino esters of aromatic acids. This fundamental structure may be represented as follows:

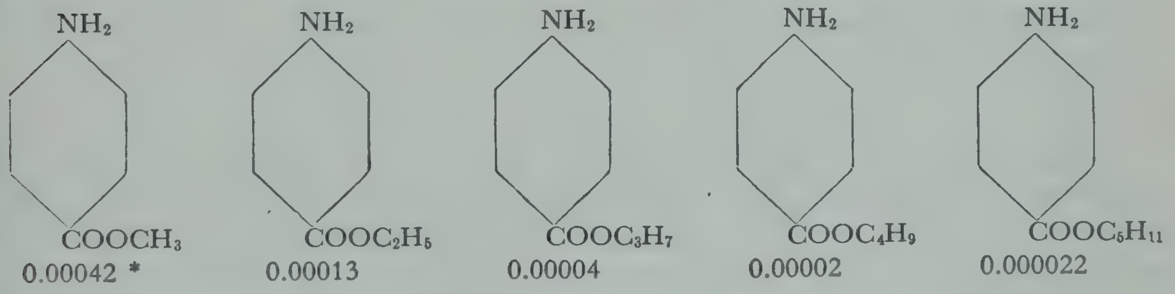


$$R\cdot COOR\cdot N\begin{matrix} R \\ R \end{matrix}$$

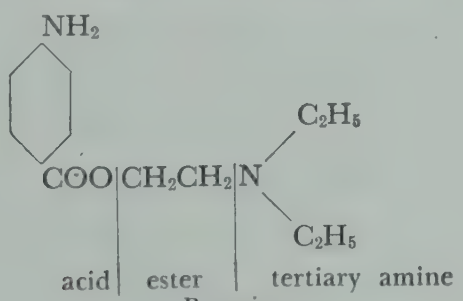
The tertiary amine is not essential for anesthetic action because simple esters are effective. Thus the esters of amino benzoic acid have the property of producing local anesthesia. In the series of esters depicted in Table 14, anesthetic activity increases with the length of the ester chain (Adams and coworkers, 1926). These particular compounds, however, are quite insoluble and their use is limited. If a tertiary amino group is introduced into the ester portion of the molecule, a more basic substance is obtained which forms soluble acid salts. For example, when a diethyl amino group is added to the ester chain of para-amino ethylbenzoate, the second compound shown in Table 14, the well-known anesthetic procaine is obtained. The structures of procaine and one of its soluble acid salts, the hydrochloride, are as follows:

Table 14

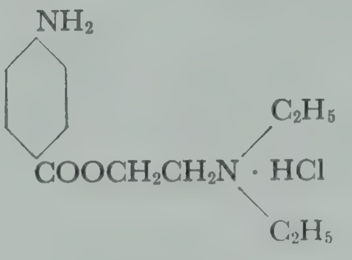
THE EFFECT OF LENGTHENING THE ESTER CHAIN ON ANESTHETIC ACTIVITY



* Minimal anesthetic concentration in mols.
Adams and associates, 1926.

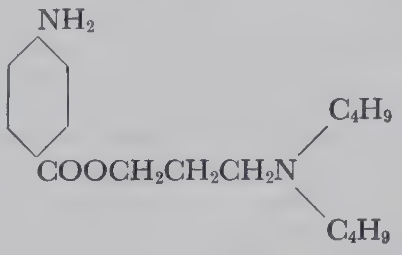


Procaine



Procaine Hydrochloride

It is evident that the procaine molecule can be divided into three main portions—the acid, the ester, and the tertiary amino group. Changes in any part of the molecule alter the anesthetic potency and the toxicity of the compound, and have led to the vast number of available local anesthetics. For example, if in procaine there is merely added one carbon atom to the ester group to form a propyl ester, and the amino group is changed from diethyl to dibutyl amine, the resulting compound is butyn, an anesthetic which is more potent, but more toxic than procaine.



Butyn

Certain general conclusions have been drawn with respect to the relationship between changes in chemical structure and pharmacological activity. Increasing the length of the ester group leads to an increase in toxicity, and thus compounds with an ethyl ester, such as procaine, exhibit the least toxicity. Concomitantly, increasing the length of the ester group decreases the basicity of the compound. As has already been explained, this leads to a more rapid liberation from the acid salt of the active free base, and therefore to a greater anesthetic potency. Also, an increase in length of the groups on the tertiary amino nitrogen decreases basicity. Both types of change have been made in the transition from procaine to butyn, and this accounts for the marked increase both in activity and toxicity of butyn as compared with procaine (Table 15).

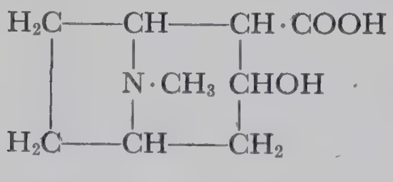
The number of compounds which conceivably could have anesthetic activity is almost infinite. Not only esters, but also ethers and amides (*see* structure of nupercaine) often exhibit this pharmacological property. The foregoing discussion merely indicates the procedures available to the chemist in exploring this fascinating field.

THE PHARMACOLOGY OF THE INDIVIDUAL LOCAL ANESTHETICS

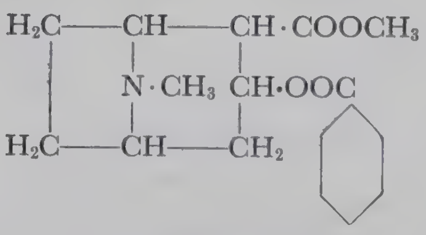
Cocaine

Source. Cocaine is obtained from the leaves of the *Erythroxylon coca* and other species of *Erythroxylon.* The tree is indigenous to Peru and Bolivia where its leaves have been used for centuries by the natives, not so much for local anesthesia as for stimulation of the central nervous system, since cocaine possesses both these properties. The native Indian runners chew the leaves in order to lessen hunger (local action on the gastric mucosa) but mainly to increase endurance (central stimulation).

Chemistry. Cocaine is benzoyl methylecgonine. Ecgonine is a base closely related to tropine, the base of atropine. Cocaine is thus an ester of benzoic acid and a nitrogen-containing base and has the fundamental structure previously described for the synthetic local anesthetics. The structural formulas of ecgonine and cocaine are as follows:



Ecgonine



Cocaine

Pharmacological Actions

The important clinical action of cocaine is its ability to block nerve conduction upon local application. Its most striking systemic effect is stimulation of the central nervous system. In addition cocaine has numerous important side-actions.

Central Nervous System. Cocaine stimulates the central nervous system from above downward. The first recognizable action is on the cortex. In man, this is manifest in garrulity, restlessness and excitement. There is some evidence that mental powers are increased. There may also be an increased capacity for muscular work probably due to a lessened sense of fatigue. Sir Arthur Conan Doyle's famous Sherlock Holmes took advantage of the central effects of cocaine, much to the perturbation of Dr. Watson. Other effects on the cerebral cortex are discussed under cocaine addiction. In animals, the cortical action is manifested mainly by increased motor activity. After small amounts of cocaine, motor activity is perfectly coordinated, but as the dose is increased the lower centers also are affected. Stimulation of lower motor centers causes tremors and convulsive movements. Cord reflexes are increased and eventually clonic and tonic convulsions appear.

The action of cocaine on the medulla results in an increase in the respiratory rate. At first the depth of respiration is unaffected but soon it is diminished so that breathing is rapid and shallow. The vasomotor and vomiting centers may also share in the stimulation, and emesis is not uncommon.

Central stimulation is soon replaced by depression. The higher centers are the first to be depressed and this may occur when the lower portions of the cerebrospinal axis are still in the stage of excitation. Thus unconsciousness and convulsions may coincide. Eventually the vital medullary centers are depressed and death results from respiratory failure.

Cardiovascular System. Small doses of cocaine may slow the heart rate as a result of central vagal stimulation. After moderate dosage, however, the heart rate is definitely increased. Tachycardia has been ascribed to vagal paralysis, but the explanation is doubtful inasmuch as vagal stimulation is still effective in slowing the heart. The increased cardiac rate probably results from increased sympathetic stimulation of both central and peripheral origin, although cocaine may also stimulate the myocardium directly. The administration of a large intravenous dose of cocaine may result in immediate death from cardiac failure due to a direct toxic action on heart muscle. Vasoconstriction due to central vasomotor stimulation, coupled with tachycardia, causes a prominent increase of blood pressure. Later the blood pressure may fall. On local application, sufficient cocaine reaches the blood vessels to cause direct vasoconstriction; but after the systemic administration of the drug, the vasoconstriction is central in origin because section of the spinal cord prevents the vascular response.

Skeletal Muscle. The relief of fatigue by cocaine has led to an investigation of the effect of the alkaloid on voluntary muscle. There is no evidence that cocaine increases the strength of muscular contraction. Therefore, it must be concluded that the ability of the drug to relieve or delay fatigue results from central stimulation which masks the sensation of fatigue.

Body Temperature. Cocaine is a marked pyretic. Three factors contribute to raise body temperature. The increased muscular activity attending stimulation by cocaine augments heat production. Vasoconstriction due to central vasomotor stimulation decreases heat elimination. Lastly there is reason to believe that cocaine has a direct action on the heat regulating centers, for the onset of cocaine fever is often heralded by a chill which is an indication that the body is adjusting its temperature to a higher level. Cocaine pyrexia is often a striking feature of cocaine poisoning, and may easily be elicited in animals by sub-lethal doses.

Sympathetic Nervous System. Cocaine has the property of potentiating the responses of sympathetically innervated organs to epinephrine, sympathin, and to sympathetic nerve stimulation. Cocaine potentiation was first observed by Frölich and Loewi in 1910, and many explanations have since been offered to account for the phenomenon. It seems well established that cocaine does not have a direct stimulating or nonspecific sensitizing action on sympathetically innervated structures, as is indicated by the lack of response to cocaine upon denervation of the effector cells. Also, cocaine potentiates both excitatory and inhibitory responses of muscles and glands to epinephrine or adrenergic nerve impulses, and it is difficult to understand how cocaine, by acting directly on the effector cells, can augment such variegated types of response. It has been suggested that cocaine enhances the production of sympathin, but this does not account for the fact that the action of injected epinephrine is potentiated. Two explanations of the sympathomimetic property of cocaine offered by Cannon and Rosenblueth (1937) which apparently can be reconciled with experimental findings are: (1) Cocaine may prevent the destruction of injected epinephrine or of sympathin, or (2) cocaine may increase the permeability of sympathetically innervated cells and thus favor the entrance of the stimulating agent. The experimental evidence of Philpot (1940) that cocaine inhibits amine oxidase, the enzyme concerned with the oxidation of epinephrine, favors the first explanation.

Local Actions. The most important local action of cocaine is its ability to block nerve conduction when brought into direct contact with nerve tissue. Cocaine blocks terminal sensory nerve fibers in a concentration as low as 0.02 per cent. Higher concentrations are required to block conduction in nerve trunks or to produce anesthesia by direct contact with mucous membranes (Table 15).

Cocaine is a "general protoplasmic poison." There is no reason to believe, however, that cocaine produces anesthesia by virtue of this property. The concentration of cocaine which is effective as an anesthetic does not damage cells. Furthermore, other local anesthetics structurally similar to cocaine do not share its toxic effect on protoplasm. The action of cocaine on protoplasm is manifest in the ability of the drug to arrest the motility of ciliated epithelial cells, leukocytes, spermatozoa, and similar unicellular structures. Putrefaction may also be delayed by cocaine.

Eye. The local action of cocaine on the eye is of particular importance because cocaine is often applied to this organ. Anesthesia of the cornea follows contact with solutions of 0.25 to 0.5 per cent. There is an accompanying constriction of the conjunctival vessels and the sclera is blanched. Anesthesia may extend to the iris. Mydriasis also occurs. The mechanism of the mydriatic action of cocaine is not understood. The pupil of the cocainized eye responds to light, and pilocarpine and physostigmine still produce miosis. If the action of atropine is superimposed on that of cocaine, further mydriasis occurs. The reverse is also true, namely, that cocaine enhances the mydriatic action of atropine. These facts are not compatible with the view that cocaine depresses the sphincter muscle of the iris. Rather mydriasis seems to be explainable on the basis of the sympathomimetic action of cocaine.

Cocaine in high concentration is capable of causing cycloplegia. The loss of accommodation is only partial, however, with concentrations used for corneal anesthesia. Cocaine has varying effects on intraocular pressure. In most instances it causes a reduction of intraocular pressure through vasoconstriction. Occasionally, however, the application of cocaine to the eye precipitates an attack of acute glaucoma. It is believed that the mydriasis may cause mechanical block of drainage from the anterior chamber.

In concentrations usually employed for anesthesia, cocaine has a deleterious effect on the cornea. The cornea may become clouded, pitted, and ulceration occasionally follows. This toxic action of cocaine is usually enhanced by the fact that the normal protective eyelid reflexes are abolished by the anesthesia of the cornea. The cornea may become dry and contaminated with foreign material. For this reason, the conjunctival sac is kept well irrigated with physiological salt solution during operations on the cocainized eye.

It is obvious that there are many properties of cocaine which detract from its value as a local anesthetic in ophthalmology. The two main drawbacks are the mydriasis and the corneal injury which it produces. Consequently cocaine has been largely replaced in this field by synthetic anesthetic agents which will be discussed.

Absorption, Fate and Excretion. The vasoconstriction occurring upon the local application of cocaine limits the rate of absorption of the anesthetic. Despite this fact, the rate of absorption may easily exceed the rate of detoxification and excretion. Consequently cocaine can be highly toxic. Cocaine is absorbed from all sites of application including mucous membranes. Absorption even occurs from the urinary bladder, especially in the presence of inflammation. When given orally, cocaine is largely hydrolyzed in the gastro-intestinal tract and rendered ineffective.

After absorption, cocaine is detoxified by the liver. It has been estimated that the liver can detoxify one minimal lethal dose of cocaine in 60 minutes. Some of the drug may be excreted unchanged in the urine. Although cocaine is destroyed much more rapidly than most alkaloids, its rate of detoxification is exceeded by many of the synthetic local anesthetics. Therefore it is more toxic after subcutaneous administration than are many of its substitutes.

Tolerance and Addiction. Cocaine is a powerful cortical stimulant and is indulged in licentiously by certain individuals to elicit this effect. Clinically, cocaine is not employed as a central nervous system stimulant because it is much too toxic for this purpose. In the discussion of morphine addiction, it is pointed out that the addict takes morphine mainly to keep free from withdrawal symptoms and to remain normal. This is not true of the cocaine addict. Cocaine causes euphoric excitement, and pleasurable hallucinations add to the satisfaction obtained. There is a feeling of great muscular and mental strength and the addict greatly overestimates his capabilities. The cocaine addict is not a normal individual but is often a dangerous and debased person. Many addicts become paranoid and suffer from ideas of persecution. As a result, they may carry firearms which they do not hesitate to use. The addict believes that he is being threatened, and that his thoughts are being read by others. Auditory, visual and tactual hallucinations are not uncommon. Black spots are seen on light backgrounds and are mistaken for insects. The sensation of something alive crawling under the skin (formication) is a common complaint. In addition to mental deterioration, the cocaine addict may experience digestive disorders, nausea, loss of appetite, emaciation, sleeplessness, tremors, and occasional convulsions.

The local actions of cocaine are prominent. If the drug is taken by subcutaneous injection, abscesses are common and multiple scars at the sites of injection may serve to identify a cocaine addict. These abscesses are the combined result of prolonged ischemia due to vasoconstriction by cocaine, protoplasmic toxicity of the alkaloid, and infection from lack of sterile technic. Many addicts take the drug by snuffing, utilizing the mucous membranes of the nose as a route of absorption. Cocaine powder is used for this purpose and is commonly called "snow." The nasal septum may occasionally be perforated due to prolonged vasoconstriction and the toxic action of cocaine.

The continued use of cocaine leads to a certain degree of tolerance. Tolerance to cocaine usually is not as marked as that which develops to morphine. Nevertheless, there have been reports of individuals taking as much as 10 grams of cocaine daily. The mechanism of tolerance to cocaine is unknown. It clearly differs from that to morphine in that it cannot be produced in laboratory animals. Psychic dependence on cocaine (habituation) is marked but physiological dependence (addiction) is not as clearly demonstrable as in the case of morphine addiction. Indeed, some investigators claim that addiction to chemicals other than the phenanthrene derivatives of opium has not been satisfactorily demonstrated. At any rate, addiction to cocaine is not as severe as that to morphine, and hence the abstinence syndrome is less marked and withdrawal less difficult.

In treating the cocaine addict, the drug should be withdrawn immediately rather than gradually, and treatment is essentially the same as that employed in morphine withdrawal. The patient suffers from severe depression, and delusions may persist for several weeks. Most cocaine addicts are psychopathic individuals and personality and environmental readjustment is as essential as medical therapy.

Acute Cocaine Poisoning. Due to the wide use of cocaine as a local anesthetic, acute poisoning from cocaine is not rare. This is largely the result of considerable individual variation in susceptibility to the drug. The fatal dose has been stated to be 1.2 grams, obviously only an approximate figure. Severe toxic effects have been reported from doses as low as 20 mgm.

The symptoms of cocaine poisoning are mainly referable to the central nervous system. The patient quickly becomes excited, restless, garrulous, anxious and confused. Reflexes are hyperactive. Headache is common. The pulse becomes rapid and the respirations irregular. A chill may herald the onset of a sudden rise in temperature. The pupils are dilated and exophthalmos occurs. Nausea, vomiting and abdominal pain are frequent. The disturbance in cutaneous sensation described under cocaine addiction also appears. Delirium, Cheyne-Stokes respiration, convulsions and unconsciousness occur terminally. Death results from respiratory arrest. Acute poisoning by cocaine runs a very rapid course. Indeed, there is a form of acute cocaine intoxication which results in almost immediate death, the patient often collapsing and dying before the physician realizes what has occurred. This type of poisoning probably results from rapid absorption of a high concentration of cocaine which is toxic to the heart.

Treatment. The specific treatment of acute cocaine poisoning is the intravenous administration of a relatively short-acting barbiturate. The intravenous route is necessary because symptoms progress with great rapidity. The same principles of dosage apply as those for the therapy of strychnine poisoning. Artificial respiration may be necessary. An important consideration is to limit absorption of the drug. The circulation from the site of cocaine absorption should be stopped by a tourniquet or in any other way possible. If the entrance of the drug into the circulation can be checked and respiratory exchange maintained, the prognosis is favorable because cocaine is destroyed fairly rapidly. There is no effective therapy for the type of cocaine poisoning characterized by sudden cardiovascular collapse and death. The *prophylaxis* of untoward responses to cocaine is discussed under the clinical uses of local anesthetics.

Preparations and Doses. *Cocaine*, U.S.P., B.P., and *Cocaine Hydrochloride*, U.S.P., B.P., are the official preparations of the alkaloid. Both are white crystalline powders. The alkaloidal base is freely soluble in organic solvents; the hydrochloride salt, in water. Cocaine is not used internally or injected. Solutions employed clinically for surface anesthesia vary from 1.0 to 4.0 per cent (cornea) to 10 to 20 per cent (nose and throat), depending on the mucosal surface being anesthetized. Epinephrine is usually incorporated in these solutions. Occasionally, dry cocaine powder is moistened with epinephrine solution to form so-called "cocaine mud" for use on the nasal mucosa, but this practice may be dangerous.

Cocaine, because of its addicting potency, is included among the drugs whose use is controlled by the Federal Narcotic Regulations.

SYNTHETIC LOCAL ANESTHETICS

The number of synthetic local anesthetics is so large that it is impossible to consider all of them. Therefore, a discussion of the individual members of this series will be limited to those which are official in the U.S.P. or have been accepted by the Council on Pharmacy and Chemistry for inclusion in the N.N.R. These sources provide a wide range from which the physician may select anesthetics for any specific purpose.

Procaine

Procaine was synthesized by Einhorn in 1905 and introduced under the trade name *novocaine*. It is probably the most important of all local anesthetics. The chemical structure of this drug has been discussed. Procaine is only one-quarter as toxic as cocaine either after intravenous or subcutaneous administration (Table 15), despite the fact that procaine is destroyed much more rapidly than cocaine in the body. After intravenous injection, the lethal dose of a drug bears no predict-

able relationship to the rate of destruction because a fatal concentration is immediately reached in the body. After subcutaneous administration, however, the attainment of toxic blood levels depends upon both the rate of absorption and destruction. Therefore, on the basis of rate of destruction, one would expect the ratio of the toxic doses of procaine and cocaine to be much greater after subcutaneous than after intravenous administration. One must remember, however, that cocaine causes vasoconstriction and is therefore slowly absorbed, whereas procaine lacks this property and gains more rapid access to the circulation. If absorption is slowed, the toxicity of procaine is greatly decreased, for procaine is rapidly destroyed by the liver, In clinical use, procaine is always administered in combination with epinephrine. In this manner its absorption is delayed, and toxic reactions are rare.

Clinical Uses. Unfortunately procaine has a limited field of usefulness as a local anesthetic. It has poor penetrating power and therefore is not serviceable for application to mucous membranes. For example, a four per cent concentration of procaine is necessary to produce minimal anesthesia of the cornea. If procaine is applied to mucous membranes, a high concentration (10 to 20 per cent) must be employed. Obviously this is an expensive procedure, and for surface anesthesia there are more effective agents. For this reason, procaine is mainly employed for injection anesthesia. The concentration used for infiltration is usually 0.25 to 0.5 per cent. For nerve block, a one or two per cent solution is commonly employed, the lower concentration being adequate for most purposes. Obviously, one should use the smallest amount of anesthetic solution compatible with successful anesthesia. A total injection of 0.5 gram of procaine during the course of a surgical procedure is a conservative amount, as for example, 50 cc of a one per cent solution. As much as three grams have been employed in a single operation without untoward symptoms.

Toxicity. Although procaine is the least toxic of all local anesthetics, it sometimes causes systemic effects in unusually sensitive individuals. Deaths have been reported from the injection of as little as 0.01 to 0.13 gram of procaine. Such responses are probably due to idiosyncrasy and fortunately are rare. Death is usually characterized by cardiovascular collapse and occurs immediately following the administration of procaine. Some individuals are extremely susceptible to the central nervous system stimulation which procaine may produce. The reaction is slow in onset and can be completely controlled by the use of barbiturates.

Preparations. Procaine is available in the form of three salts—the hydrochloride, borate, and nitrate. Only the hydrochloride salt is official in the U.S.P. and B.P., the other two being N.N.R. preparations. These salts are practically identical in action. A point to bear in mind is the fact that the borate radical so increases the molecular weight of the compound that the concentration employed must be increased by 50 per cent. Procaine is marketed with or without epinephrine in a wide range of doses and concentrations. It is dispensed in ampules as dry white crystals or in solution, and in tablet and powder form.

Butyn

Butyn, N.N.R., is closely related chemically to procaine, being the dibutylaminopropyl ester of para-aminobenzoic acid. Its action as an anesthetic agent, however, may be more closely compared with that of cocaine.

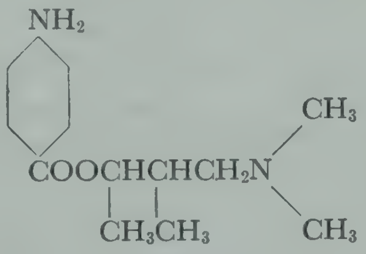
After intravenous injection, cocaine and butyn have the same toxicity. After subcutaneous administration, butyn is the more toxic (Table 15). This is probably due to the fact that cocaine is more slowly absorbed rather than that butyn is more difficult to destroy. The anesthetic potency of butyn is practically the same as that of cocaine. Butyn penetrates mucous membranes readily, and its chief use is to produce surface anesthesia. Its high toxicity contraindicates its employment in procedures requiring injection of the anesthetic.

Butyn has largely replaced cocaine as a surface anesthetic inasmuch as it possesses most of the advantages and few of the disadvantages of cocaine. For example, it has good penetrativeness, rapid onset of action and long duration of anesthesia. When applied to the eye it neither causes ischemia nor affects the pupil. The absence of mydriasis is an advantage of considerable importance in operations on the iris. Butyn is also less damaging than cocaine to the cornea.

For surface application butyn is usually used as the sulfate salt in a two per cent solution. It is also employed in an ointment base for local application to the eye. Although butyn is occasionally injected, its high toxicity makes such a procedure dangerous. Safer agents are available for injection anesthesia.

Tutocaine

Tutocaine, N.N.R., is another ester of para-aminobenzoic acid and a tertiary amino base. It has the following structural formula:

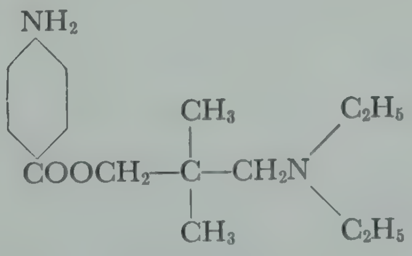


Tutocaine

Tutocaine is slightly less toxic than cocaine after intravenous injection and less than half as toxic as cocaine after subcutaneous administration. It is comparatively safe for injection anesthesia inasmuch as concentrations of 0.2 per cent are anesthetic. It is effective after topical application, and for use in the eye a one per cent solution is sufficient. Two to five per cent solutions are used to produce anesthesia of the nose and throat and it is claimed that the higher concentration shrinks the mucous membrane. For application to the urethra, the recommended concentrations range from one-half to two per cent depending upon the nature of the surgical procedure. It is available as the hydrochloride salt.

Larocaine

Larocaine, N.N.R., is another member of the procaine family of local anesthetics, being a tertiary amino ester of para-aminobenzoic acid. Its structural formula is as follows:

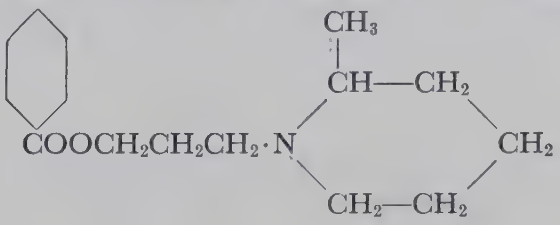


Larocaine

Larocaine is active both as a surface and an injection anesthetic. It is twice as potent as cocaine on the eye and has none of the undesirable effects of the latter. It also has a longer duration of action. When compared with procaine, larocaine is more active as a block anesthetic. However, it is as toxic as cocaine upon intravenous administration and only slightly less toxic after subcutaneous injection. Therefore, it should be injected with caution. For corneal anesthesia larocaine is used in two to five per cent concentrations. In the nose and throat, five to 10 per cent solutions are employed. A one per cent solution is used in urological work. For injection anesthesia, strengths varying from one-quarter to two per cent are recommended. The available salt is the hydrochloride.

Metycaine

Metycaine, N.N.R., is an ester of benzoic acid and a base containing nitrogen in the form of a methyl-piperidino ring. It has the following structural formula:

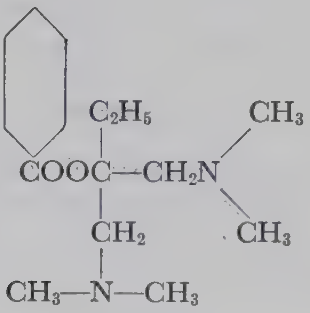


Metycaine

Metycaine is suitable for topical anesthesia and for the production of nerve block. It is about three times as toxic as procaine upon intravenous injection, but approaches the toxicity of procaine after subcutaneous administration. Metycaine is used in the eye as a two per cent solution or a four per cent ophthalmic ointment. In the nose and throat, two to 10 per cent solutions are applied. For anesthetizing the mucous membranes of the genitourinary tract, concentrations ranging from one to four per cent have been employed. For injection anesthesia, one-half to one per cent solutions are used. Metycaine is obtainable as the hydrochloride salt.

Alypin

Alypin, N.N.R., is also a tertiary amino ester of benzoic acid and has the following structural formula:

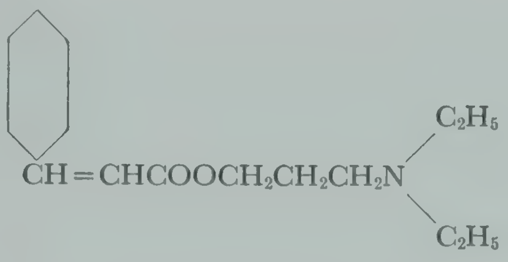


Alypin

Alypin is quite as toxic as cocaine and its use should therefore be limited to surface application to mucous membranes. When applied to the eye it does not have the disadvantages of cocaine. For ophthalmological purposes it is used in a concentration of two to four per cent. In rhinolaryngology, five to 10 per cent solutions may be employed. Alypin has also been used in urology in concentrations of one to four per cent. Although alypin has been employed for injection anesthesia in concentrations of one-half to two per cent, it is probably too toxic to be used in this manner. Alypin is available as the soluble hydrochloride salt.

Apothesine

Apothesine, N.N.R., is the diethylaminopropyl ester of cinnamic acid and has the following structure:

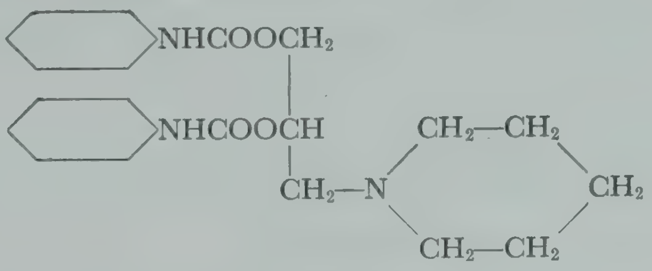


Apothesine

There is little to be said in favor of apothesine. It resembles procaine in that it is not suitable for surface application to mucous membranes, and therefore it can be used only for injection anesthesia. It is twice as toxic as procaine and no more active. Apothesine is also slower in action than procaine and is apt to produce greater irritation. Its duration of action, however, is longer. For injection anesthesia, apothesine is used in concentrations ranging from 0.5 to 2.0 per cent. The available soluble salt is the hydrochloride.

Diothane

Diothane, N.N.R., is a phenylurethane derivative, and it can be noticed in the following structural formula that the nitrogen of the ester grouping is contained in a piperidino ring, a grouping also present in metycaine.

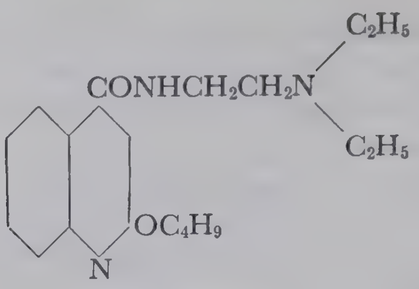


Diothane

The toxicity of diothane is less than that of cocaine and greater than that of procaine. It is active both as an injection anesthetic and after topical administration to mucous membranes. An unusual feature is the long duration of its action. Thus diothane has been used in such operations as hemorrhoidectomy or amputation of limbs. It is usually employed in a one per cent solution. Because of its fairly high toxicity, the total amount injected should be kept as low as possible. Diothane is available in solution as the hydrochloride salt and as a one per cent ointment.

Nupercaine

Nupercaine, N.N.R., is a quinoline derivative of high toxicity and high anesthetic potency. It has the following structure:



Nupercaine

It is about six times as toxic as cocaine upon intravenous injection, and twelve times as toxic as cocaine after subcutaneous administration. However, the high anesthetic potency of nupercaine suggests that it may have a greater margin of safety than cocaine (Table 15). Nupercaine has been used for all types of local anesthetic procedures. It is the most potent and most toxic of the commonly employed local anesthetics, and several deaths have been reported from its use. Although tissue damage has followed the employment of nupercaine, there is no reason to believe that it is more injurious to tissue than are other local anesthetics.

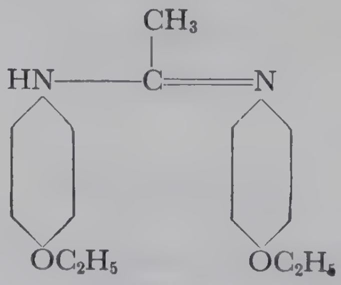
There is evidence that nupercaine is rapidly destroyed by the liver. It also provides anesthesia of long duration. Some surgeons recommend that advantage be taken of these two features by administering a preliminary anesthetizing dose of nupercaine thirty minutes before operation. At the time of operation, this preliminary anesthetic dose will still be effective with respect to anesthesia, and yet the material absorbed will have been destroyed. This permits further administration of nupercaine which results in still more effective anesthesia.

Nupercaine is employed for injection anesthesia in 0.05 to 0.1 per cent solution (1:2000 to 1:1000). Its combination with epinephrine is important inasmuch as low concentrations are likely to cause some capillary dilatation. When used in 0.1 per cent concentration, the total amount of nupercaine solution injected should not exceed 100 cc. Some anesthetists consider this amount too high. Death has been reported from the administration of 135 cc of a 1:1000 solution. For surface anesthesia, nupercaine may be employed as follows: cornea, 0.1 per cent solution; nose and throat, 0.5 to 2.0 per cent solution; urethra, 0.05 to 0.2 per cent solution; skin, 0.5 to 1.0 per cent ointment. Nupercaine is marketed as the soluble hydrochloride salt.

In view of its high toxicity, nupercaine should be used only by those thoroughly familiar with the drug and with the technic of local anesthesia.

Phenacaine

Phenacaine was one of the earliest local anesthetics to be introduced and is official in the U.S.P. as the hydrochloride salt. It differs greatly in chemical structure from the majority of local anesthetics thus far described. Phenacaine is a derivative of phenetidin and was built up from this structure because of the known antineuralgic effects of the phenetidin molecule. Phenacaine is not an ester, as can be seen from its structural formula:



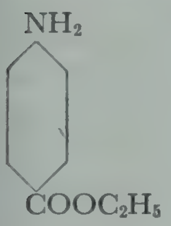
Phenacaine

Upon intravenous injection phenacaine is as toxic as cocaine. It is not as readily destroyed as cocaine in the body, as is indicated by the fact that its subcutaneous toxicity is twice as great as that of cocaine. For this reason, it is unsuitable for injection and its use is limited to topical application, especially to the eye. A one per cent solution is employed. Phenacaine is slightly irritating and anesthesia is preceded by smarting. *Holocaine* (N.N.R.) is a brand of phenacaine.

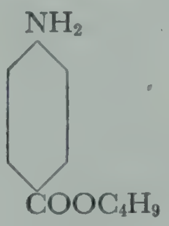
Anesthetics of Low Solubility

This group of local anesthetics is characterized by the fact that its members are poorly soluble in water. Obviously, this seriously limits their usefulness, but it opens special fields of application. As a result of their insolubility, these compounds can be applied directly to wounds and ulcerated surfaces because they are not absorbed with sufficient rapidity to be toxic. Thus they remain localized at the site of application for long periods of time, which accounts for their sustained anesthetic action.

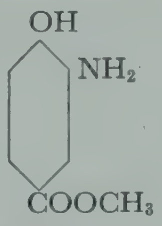
Chemically, the poorly soluble local anesthetics are closely related to the procaine group in that they are esters of aminobenzoic acid. They differ in being simple esters and contain no basic nitrogen grouping. Consequently they do not form soluble acid salts. The most important members of the series are *Ethyl Aminobenzoate* (Benzocaine), U.S.P., B.P., also known as Anesthesin; *Butesin*, N.N.R.; *Butesin Picrate*, N.N.R.; *Orthoform*, N.N.R. (Orthocaine, B.P.). All are white, crystalline, insoluble powders with the exception of butesin picrate which is yellow and amorphous. They have the following structural formulas:



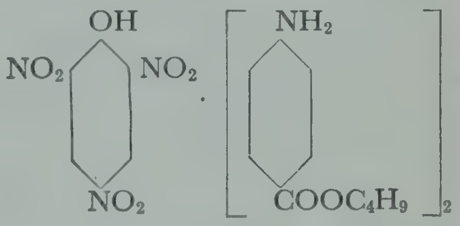
Ethyl Aminobenzoate



Butesin



Orthoform

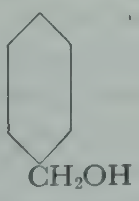


Butesin Picrate

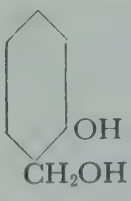
The aforementioned compounds may be applied as dusting powders, undiluted or diluted with sterile talc. They are soluble in oil and may be incorporated in oily solutions, ointments, and suppositories. Specific indications for these drugs are described under the clinical uses of the local anesthetics. Butesin picrate is unique in that it incorporates the anesthetizing properties of butesin with the antiseptic properties of picric acid.

Aromatic Alcohols

Certain aromatic alcohols have the property of producing local anesthesia. The two most important are *Benzyl Alcohol*, N.N.R., a colorless liquid, and *saligenin* (salicylic alcohol), a colorless crystalline solid soluble in water to the extent of 1:15. These compounds have the following structural formulas:



Benzyl Alcohol



Saligenin

The anesthetic potency of benzyl alcohol was studied by Macht (1918). In favor of benzyl alcohol is the fact that it is relatively non-toxic, being converted to hippuric acid in the body. On the other hand, the anesthesia following its use is uncertain, and accompanying its injection there may be subcutaneous edema and pain. Benzyl alcohol is soluble in water to the extent of four per cent, and in this concentration it has a brief anesthetic action after topical application to mucous membranes. One to four per cent solutions may be used for injection anesthesia. Benzyl alcohol has been employed in the form of an ointment or lotion to control cutaneous itching. This constitutes its most legitimate use. A simple antipruritic lotion can be made by combining equal parts of benzyl alcohol, ethyl alcohol and water.

Saligenin is also relatively non-toxic. Two per cent solutions may be used for injection anesthesia and four to eight per cent solutions anesthetize the urethra sufficiently for purposes of cystoscopy. The relationship between saligenin and the salicylates is discussed elsewhere.

Quinine Salts

Certain salts of quinine are sometimes employed as local anesthetics. *Quinine and Urea Hydrochloride,* U.S.P. is the preparation of choice because it is the most soluble and least irritating. However, it is acid in solution and irritates before it produces anesthesia. The anesthetic action of quinine and its derivatives is directly proportional to its toxicity for protoplasm. There is reason to believe, therefore, that the action of quinine on sensory nerves is non-selective and is merely the result of the toxic action of the alkaloid on protoplasm. The anesthetic action of quinine is of long duration and several weeks may elapse before nerve function is completely restored. In contrast to other local anesthetics, quinine has a pronounced effect on the tissues at the site of injection, and edema and exudation accompany its use. Often there is an area of hyperesthesia surrounding the area of anesthesia. Quinine may be of particular value in conditions where anesthesia of long duration is desired as in pruritus ani. If the concentration of the solution employed is greater than 0.5 to 1.0 per cent, extensive necrosis may follow. In ointment form, quinine has been employed to anesthetize painful hemorrhoids. An advantage of quinine salts as local anesthetics is their relatively low systemic toxicity. The pharmacology and therapeutics of quinine and its salts are described elsewhere.

CLINICAL USES OF LOCAL ANESTHETICS

The following discussion can do no more than indicate the fields of usefulness of the local anesthetics, the criteria for their selection, the precautions to be observed in their employment, and the general principles of technic. Special texts must be consulted for the practical details of local anesthetic procedures.

It should always be remembered that the local anesthetics are toxic drugs, and certain precautions should be observed to lessen their toxicity.

Preliminary Sedation. Most local anesthetics are central nervous system stimulants, and they are likely to produce convulsions, especially if they are employed in large amounts. In sensitive individuals, convulsions may follow the administration of relatively small doses. Although it is possible by means of central depressants to control such reactions after they have become manifest, a far safer procedure is routinely to precede the administration of a local anesthetic with a sedative. The barbiturates are the preparations of choice. The barbiturate selected should have a duration of action sufficiently long to insure that the complete absorption and destruction of the local anesthetic have occurred before the effects of the sedative have worn off. Barbital is often administered in a dose of 0.5 to 0.67 gram one hour before the local anesthetic is given. Phenobarbital in a dose of 0.15 to 0.2 gram is also serviceable.

Choice of Anesthetic. When a local anesthetic is to be injected, the least toxic one should be employed. Procaine is considered the safest agent available for this purpose. Procaine should be employed in the lowest concentration and the smallest total amount compatible with the needs of the surgical procedure. For anesthetizing mucous membranes, agents of greater penetrative power than procaine are necessary. Cocaine is widely used as a surface anesthetic but several synthetic substitutes are available and on occasion preferable. No single compound is outstanding for surface anesthesia. The clinician would be wise to limit his choice to one or two Council-accepted agents that have stood the test of clinical trial. In this way he can become thoroughly familiar with their effective concentrations, limitations and toxicity. A working knowledge of one good surface anesthetic and procaine is sufficient for practically all local anesthetic procedures. The clinical trial of new local anesthetic agents should be restricted to experts in this field.

Due to the high incidence of accidents from the use of local anesthetics, the American Medical Association appointed a special committee to investigate the problem. This committee (Mayer, 1924) made several recommendations of which the following are the more important: (1) Cocaine and butyn should be restricted to surface application; (2) the total amount of cocaine used should not exceed 0.1 gram; (3) procaine may be employed as an injection anesthetic, but its concentration should be limited to 1.0 per cent; (4) anesthetic agents should not be injected into the urethra if there is trauma, inflammation or stricture (*see* Report of the Council, 1939); (5) precautions should be taken not to confuse cocaine and procaine, inasmuch as a number of fatalities have occurred from this error.

Technics for Local Anesthesia

Surface Anesthesia. The aqueous solutions of salts of local anesthetics do not penetrate the intact epidermis. Preparations of the anesthetic bases in ointments, however, accomplish this to a limited extent. For application to wounds and ulcers for the relief of pain, the insoluble compounds already described are the preparations of choice. They are relatively safe and, if properly used, do not interfere with tissue healing. After prolonged administration there is some evidence that they may produce tissue damage and delay healing. Their ingestion for the relief of gastric pain or vomiting has little rational basis. A more legitimate use is found in the relief they afford after tooth extraction, tonsillectomies, etc. They are frequently incorporated in troches for the symptomatic relief of sore throat.

Anesthesia of the mucous membranes of the nose and throat can be produced by painting or spraying solutions of any of the agents which penetrate these membranes. The concentrations employed have already been given for the individual anesthetics. The mucous membranes of the urogenital tract are often anesthetized prior to instrumentation or surgical procedures. The intra-urethral injection of local anesthetics has led to many accidents, and the precautions cited should be rigidly observed. The cornea of the eye is easily anesthetized by topical application of solutions of local anesthetics. The more potent agents can be employed with safety for there is little absorption from this site. The advantages of butyn over cocaine for corneal anesthesia have already been described Anesthetic agents may also be applied to the eye and mucous membranes in the form of ointments.

Infiltration Anesthesia. This technic has for its purpose the anesthetizing of nerve endings by their direct exposure to the drug. The solution may be injected into the papillary layer of the skin (endermic injection). The onset of cutaneous anesthesia is almost immediate and very little of the anesthetic need be employed. Subcutaneous injection of the drug carries the anesthesia to a deeper level but allows for greater absorption. In addition, a short interval is required before the onset of anesthesia. After the skin is anesthetized, the deeper structures may be infiltrated if necessitated by the surgical procedure. A type of infiltration commonly employed is known as *ring block.* In this procedure the anesthetic is not injected at the site of operation, but instead is infiltrated subcutaneously in a circular manner around the line of incision. This effectively blocks all sensory nerves supplying the skin over the operative field.

Block Anesthesia. The technics of block anesthesia have greatly increased the usefulness of local anesthetics. In block anesthesia the transmission of impulses in the nerve trunks supplying the operative area is interrupted. Obviously the extent of the anesthesia produced depends upon the distribution of the nerves which are blocked. In the case of a peripheral nerve, only a discrete area is anesthetized. On the other hand, the transmission of nerve impulses in the spinal cord itself may be blocked. The extent of the anesthesia depends upon the segments of the spinal cord which are involved. In the production of nerve block, two or three cc of a one per cent solution of procaine (or an equipotent concentration of any other drug of choice) are injected in the immediate vicinity of the nerve trunks which supply the area of operation. In many of these block procedures, experience is necessary to insure success and more and more the responsibility for administration of local anesthetics is being delegated to specialists in this field.

Paravertebral Block. This is an extensive form of block anesthesia in which the spinal nerves are blocked at their point of exit from the intervertebral foramina. It is usually employed only by specialists in anesthesia. It may be of particular value in certain cases of thoracic surgery. For operations in the lower abdomen, however, spinal anesthesia is simpler and probably safer.

Trans-sacral block is used for anesthetizing the bladder, prostate, rectum and perineum. The anesthetic is injected around the sacral nerves at their points of exit from the sacral foramina. Multiple injections and a high degree of skill are required to block all branches of these nerves. An alternate method of producing sacral block is to pass a needle through the sacral hiatus and inject the anesthetic solution into the epidural space.

Spinal Anesthesia. Spinal anesthesia is a special type of extensive block anesthesia. The first spinal anesthesia in man was performed by Bier in 1899. For a short time thereafter, this type of anesthesia enjoyed popularity. A high incidence of deaths, however, brought it into disrepute. Two factors especially contributed to the dangers attending the early use of spinal anesthesia. The anesthetic agent then employed, cocaine, was too toxic to be administered in this manner. Also, the physiological effects of a local anesthetic in the spinal canal were not appreciated and consequently no precautions were taken to circumvent the attending dangers.

Action of Local Anesthetics in the Spinal Canal. The action of local anesthetics in the spinal canal is to block nerve conduction. If it were possible to confine the action to a desired locus, the performance of spinal anesthesia would be simple. In actual practice, many factors operate to complicate the procedure. The local anesthetics tend to spread along the length of the spinal canal. All types of nerve fibers—sensory, motor, somatic and autonomic—are functionally blocked and this may result in a severe if not fatal incapacitation of the vital processes.

Sequence and Duration of Anesthesia. Following the intrathecal injection of a local anesthetic there is a definite sequence in which the various types of nerve structure are paralyzed. In human beings, the sensory nerves are the first to be affected. Sensory block occurs within two to eight minutes (average four). Autonomic fibers are blocked about one minute later. This is manifested by a rise in skin temperature due to the involvement of the vasoconstrictor fibers of the anterior nerve roots. Within a few minutes thereafter motor paralysis appears. As the anesthesia wears off, function is regained in the opposite order, motor activity being the first to be restored. The duration of spinal anesthesia is often shorter than is desirable. For example, procaine anesthesia lasts for only one hour following the administration of concentrations compatible with safety. Other drugs act for longer periods, nupercaine having the greatest duration (three hours). Duration of anesthesia can be lengthened by increasing the concentration of the anesthetic solution.

Level of Anesthesia. Local anesthetics are usually injected into the subarachnoid space between the conus medullaris and the terminal portion of the spinal canal, in order to avoid injury to the spinal cord. In the adult, therefore, the injection is ordinarily made through one of the vertebral interspaces between the first and fourth lumbar levels. Obviously upward diffusion of the anesthetic agent must take place in order for extensive sensory paralysis to result, and the topography of the anesthetic area depends upon the extent of this diffusion. The skillful anesthetist limits the area of anesthesia to the minimum necessary for the contemplated surgical procedure. The upward passage of an anesthetic agent in the spinal canal depends upon a multitude of factors, among them being the diffusion currents within the subarachnoid space, the specific gravity of the injected solution, the plane of the spinal canal relative to the horizontal, movements of the patient, etc. The following are the more important procedures utilized to control the level of anesthesia.

Site of Injection. Inasmuch as the sites of injection are limited, this is a relatively unimportant factor. Some anesthetists inject at the same level and utilize other variants to control the level of anesthesia. Others vary the site of injection from the extremes of L_5 for operations on the perineum to D_{12} for upper abdominal operations.

Volume of Solution. Local anesthetics are usually dissolved in spinal fluid, previously withdrawn for this purpose. The volume of the anesthetic solution which is injected greatly influences the level of anesthesia obtained. The area of anesthesia becomes more extensive as the volume of anesthetic solution is increased. The volume injected is varied in clinical practice between one and 10 cc or more, depending upon the level of anesthesia desired and the extent to which this variable is being utilized to control the anesthesia.

Total Amount of Anesthetic Agent. The total amount of anesthetic agent used must be sufficient to provide a concentration of the drug in the spinal fluid capable of producing nerve block and also to permit an adequate duration of anesthesia. The greater the amount of anesthetic agent injected, the greater is the area anesthetized and the longer the duration of anesthesia. Low abdominal operations require a relatively small amount of drug for little upward diffusion is necessary and the anesthetic agent does not become diluted with a large volume of spinal fluid. As the extent of the area to be anesthetized is increased, the total dose must be raised. The degree to which the total dose is varied depends upon how much this particular factor is being used to control the level of anesthesia. Obviously the relative doses of the individual anesthetic agents vary with their potency.

Speed of Injection. Solutes diffuse slowly in the spinal fluid unless currents are set up to speed the process. For example, the force of injection of the anesthetic agent may be an important factor in determining the extent of diffusion. The more rapid the rate of intrathecal injection, the higher is the level of anesthesia obtained. In practice, however, a slow rate of injection is utilized because the level of anesthesia cannot be accurately regulated by varying this factor.

Position of Patient. Anesthetic solutions dissolved in spinal fluid naturally have a specific gravity higher than that of the spinal fluid. Therefore the rate of diffusion can be influenced by the position of the patient. The level of anesthesia can be raised by placing the patient in the Trendelenburg position immediately after injection. A horizontal position minimizes upward diffusion. Some anesthetists vary the specific gravity of the anesthetic solution by the addition of such a substance as glucose.

* From data presented by Saklad (1936).

Table 16, compiled from data presented by Saklad (1936), illustrates different technics for the administration of spinal anesthesia and the utilization of the various factors outlined for the control of the level of anesthesia.

Toxic Effects of Spinal Anesthesia. Respiration. A local anesthetic in the spinal canal can depress respiration in two ways. As the drug diffuses upward into the thoracic area, the motor nerves to the muscles of respiration are paralyzed. The intercostal nerves are successively blocked and respiration becomes progressively more shallow and diaphragmatic in nature. When the roots of the phrenic nerves are reached, diaphragmatic breathing stops. If an anesthetic is injected in the cervical region of the cord and allowed to diffuse downward, the movements of the diaphragm cease earlier than those of the intercostal muscles. If an anesthetic drug is injected into the cisterna magna or the fourth ventricle all types of respiratory movements cease simultaneously after a very short interval, signifying that medullary paralysis has been the cause of the respiratory failure (Hill and Macdonald, 1935) (Figure 25). There is a controversy in regard to this last point, some investigators presenting experimental evidence suggesting that local anesthetics may be applied directly to the medulla without causing paralysis of vital centers. Without pursuing this question further, it may be stated that exception has been taken to the technic and interpretation of those experiments which minimize the vulnerability of the medulla to the action of local anesthetics. It is difficult to see why the medulla should respond differently to local anesthetics than do other portions of the cerebrospinal axis.

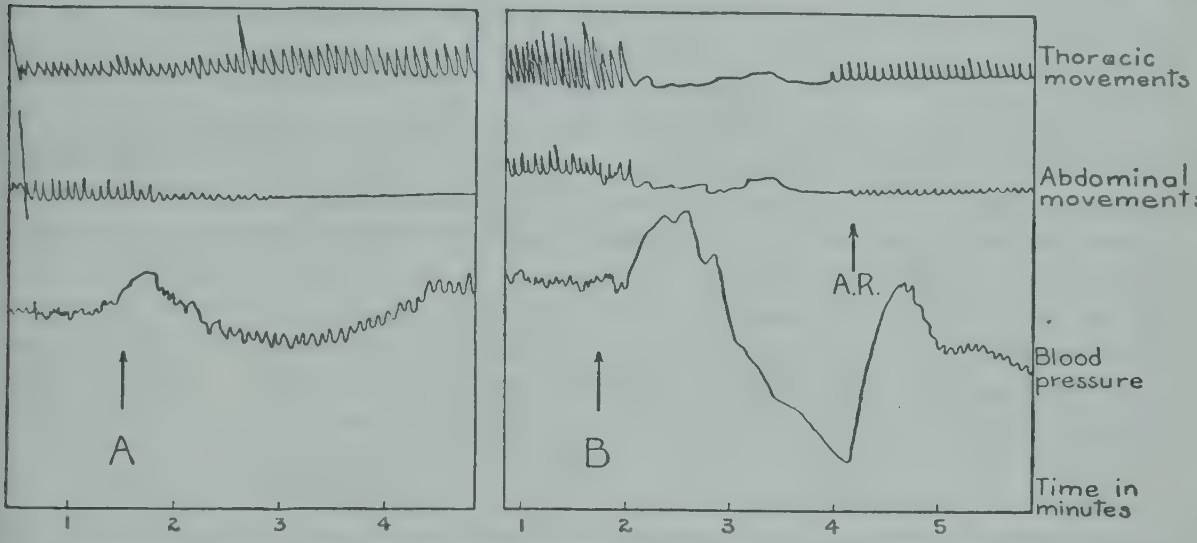

FIGURE 25. *The effects on respiratory movements of procaine injected into the subarachnoid space of chloralosed cats.*

At *A*, 10 mgm of procaine benzoate in 0.1 cc of solution are injected intrathecally at the level of C_3. The anesthetic blocks the roots of the phrenic nerves, and abdominal respiration ceases in less than two minutes due to paralysis of the diaphragm. There is a compensatory increase in thoracic respiration and the blood pressure is thereby sustained. At *B*, the same dose of procaine is injected into the cisterna magna and gains direct access to the respiratory center. All respiratory movements are immediately slowed and then simultaneously and rapidly paralyzed. The transient rise in blood pressure is due to anoxia secondary to apnea, and the subsequent marked fall in pressure is checked by the administration of artificial respiration (A.R.). (After Hill and Macdonald, 1935. Courtesy of the *Journal of Pharmacology and Experimental Therapeutics.*)

The susceptibility of the respiratory nerves and centers to the action of local anesthetics is one of the greatest handicaps to the extensive clinical employment of spinal anesthesia. In order to attain anesthesia adequate for upper abdominal surgery, the spinal block must extend to the level of T_5. In practice it often rises above this level and respiration may be seriously embarrassed. Obviously spinal anesthesia cannot be safely employed for surgery above the level of the abdomen.

During the first half-hour of spinal anesthesia the anesthetist is constantly on the alert to ascertain how high motor paralysis has extended. Signs of impending respiratory paralysis are the diminution of thoracic respiration with increasing diaphragmatic excursions, loss of spoken voice, dilatation of the alae nasi, and the use of the accessory muscles of respiration with dropping of the jaw with each respiration (Saklad, 1936). A failing respiration during spinal anesthesia calls for physical measures rather than drug therapy inasmuch as the failure is on the motor side and cannot be influenced by respiratory stimulants. If some muscle function remains, the administration of pure oxygen may be sufficient to keep the blood adequately oxygenated. Complete muscular paralysis necessitates artificial respiration. An intratracheal tube should be passed to assure an open airway.

Circulation. Following the intrathecal injection of a local anesthetic in a concentration adequate to produce nerve block, there is a progressive fall in systemic blood pressure. This is due mainly to a loss of vasomotor tone which follows the paralysis of the vasoconstrictor fibers in the anterior nerve roots. Other factors which may contribute are the loss of skeletal muscular tone in the anesthetized areas and a certain degree of anoxia due to respiratory depression. The fall in blood pressure is progressive for the reason that reflex control of blood pressure is inoperative due to the extensive paralysis of the sympathetic vasomotor outflow. For example, Heymans and coworkers (1933) have shown that when a local anesthetic rises sufficiently high in the spinal canal to produce sensory paralysis at the level of the umbilicus, the blood pressure may not be seriously depressed but carotid sinus reflexes no longer operate effectively. When sensory anesthesia reaches the level of the clavicle, there is a profound and prolonged fall in blood pressure and the carotid sinus reflexes are completely lost.

Despite the fact that the cardiac nerves are not paralyzed at levels of spinal anesthesia which cause a significant fall in blood pressure, the heart rate is not reflexly speeded. The beat, however, is forceful and the pulse pressure is high. Some investigators have attributed this to a vagal stimulation but the cause is not clear. Seevers and Waters (1932) have shown that during spinal anesthesia in dogs there is a rise in venous pressure. This promotes good filling of the right heart, forceful ventricular contractions, and adequate cardiac output, factors which may account for the relatively slow cardiac rate.

The lack of compensatory circulatory reflexes under spinal anesthesia renders the patient especially susceptible to hemorrhage inasmuch as the volume capacity of the circulatory system cannot be reduced to meet a diminished blood volume. Under such circumstances, venous pressure falls and tachycardia results. This is a dangerous sign during spinal anesthesia. Immediate measures to maintain blood volume should be taken (page 587).

The fall in blood pressure during spinal anesthesia would at times be an insurmountable obstacle to the clinical use of this type of block were it not for the fact that it can be successfully combated by the use of drugs. A sympathomimetic stimulant of long duration of action is indicated and the drug which best answers the purpose is ephedrine. Ephedrine is routinely administered by most anesthetists prior to the induction of spinal anesthesia. The doses employed vary between 50 and 100 mgm. The drug compensates sufficiently for the extensive sympathetic vasomotor block to prevent any significant fall in blood pressure. Ephedrine medication may be eliminated when the action of the local anesthetic is confined to the lower portions of the cord.

The foregoing views on the mechanism of the circulatory changes during spinal anesthesia are those which are accepted by the majority of investigators. In a significant paper, however, Smith, Rovenstine, Goldring, Chasis and Ranges (1939) seriously question the validity of these concepts, and present evidence in favor of the interpretation that circulatory failure during spinal anesthesia is the result of a pooling of blood in the venous side of the circulatory tree subsequent to the loss of tone of skeletal muscle.

Smith and coworkers experimented on normal, unoperated human subjects under spinal anesthesia. That the sympathetic fibers in the anterior nerve roots were completely paralyzed was demonstrated by the fact that the subjects showed no reflex circulatory response to such procedures as postural changes and the inhalation of carbon dioxide. The authors then showed that, despite the sympathetic block, their subjects gave little evidence of arteriolar dilatation. They present the following arguments: (1) Although there was a fall of blood pressure during spinal anesthesia, the pressure responses observed from the point of view of hemodynamics were not consonant with arteriolar dilatation, in that the diastolic pressure was well maintained while the systolic and pulse pressures were reduced. The authors point out that moderate arteriolar dilatation would be revealed by a substantial increase in pulse pressure at the expense of the diastolic pressure. (2) The changes in blood pressure observed could be explained on the basis of what would be expected when the peripheral resistance remains relatively unchanged while the cardiac output is reduced. Smith and coworkers believe that in their studies a decreased venous pressure accounted for a reduced stroke volume and cardiac output. Although they made no measurements of cardiac output, they cite from the literature many instances in which spinal anesthesia was shown experimentally to be associated with a reduced cardiac output. The decrease in venous return was attributed by Smith and coworkers to the loss in tone of skeletal muscle resulting in a dilatation of capillaries, venules and veins. In one of their patients, tilting at an angle of 20 degrees from the horizontal resulted in circulatory collapse (Figure 26). The parallelism between this response and nitrite syncope (Figure 60) is obvious. The mechanism of nitrite syncope is also believed to be due to a pooling of blood in the venous system (page 556). (3) Careful measurements of the blood flow through the kidney failed to reveal significant changes in renal circulation incident to blocking the efferent sympathetic pathways to the organ by spinal anesthesia.

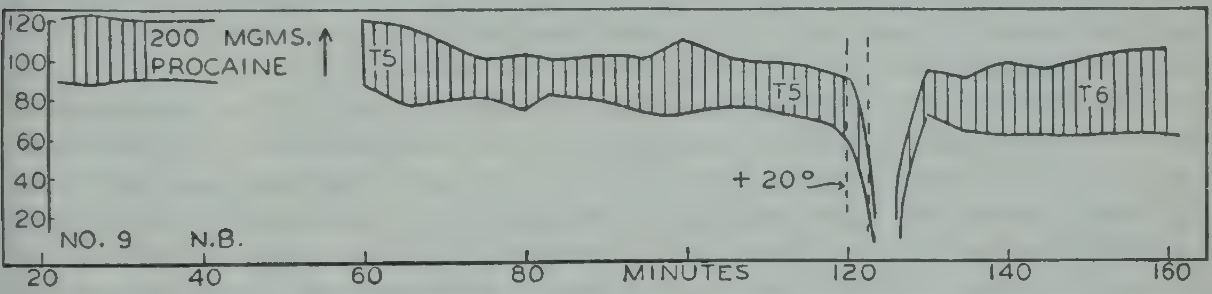

FIGURE 26. *The effect of spinal anesthesia and subsequent postural changes on blood pressure.*

Normal subject under spinal anesthesia (procaine). The effect of the anesthetic in the spinal subarachnoid space while the subject was in the horizontal position was to decrease the mean blood pressure from 106 to 90 mm of mercury. Tilting toward the upright position resulted in syncope, which may be attributable to venous stagnation aggravated by gravity. Note the similarity to nitrite syncope (Figure 60). (After Smith, Rovenstine, Goldring, Chasis and Ranges, 1939. Courtesy of the *Journal of Clinical Investigation.*)

Smith and coworkers agree that spinal anesthesia blocks sympathetic efferent fibers. They take exception, however, to the physiological significance which other investigators place upon such a block. It is their claim that after autonomic denervation the arterioles of the splanchnic viscera and probably skeletal muscles possess sufficient autonomy to maintain a normal blood pressure. They make this claim on the basis of their own observations on the renal circulation, and from an exhaustive summary of the literature on this subject.

It is difficult on the basis of the interpretation of Smith and associates to explain the salutary effects of ephedrine during spinal anesthesia. Also one would expect an increased heart rate during spinal anesthesia attending a fall in systolic blood pressure occasioned by a decrease in venous return and cardiac output. On the other hand, there is little doubt that, attending arteriolar dilatation, decreased peripheral resistance, and adequate venous return, an increase in pulse pressure should readily be noted. Accurate measurements of venous pressure and cardiac output on a large number of patients under spinal anesthesia must be awaited before a final conclusion can be reached.

Nerve Injury. Rarely spinal anesthesia is followed by radiculitis and myelitis. These infrequent toxic sequelae are attributed by some investigators to faulty technic but others believe that they arise from a direct toxic action of local anesthetics on nerve tissue. This subject has been extensively reviewed by Light and coworkers (1940).

Systemic Toxicity. Absorption of local anesthetics from the spinal canal does not readily occur. Nevertheless, intrathecal injection of anesthetic agents occasionally may give rise to characteristic systemic poisoning. Inasmuch as the amounts of drug injected for spinal anesthesia are much lower than those used for the usual types of infiltration or block anesthesia it must be assumed that such responses occur mainly in hypersensitive individuals.

Advantages of and Indications for Spinal Anesthesia. Spinal anesthesia may have definite advantages over general anesthesia. It gives an extreme degree of muscular relaxation which is obtainable only under the deepest planes of general anesthesia. The patient does not lose consciousness. In some individuals this fact removes a source of apprehension. Patients with cardiac disease may tolerate spinal anesthesia better than general anesthesia. In the presence of pulmonary disease such as bronchitis, bronchiectasis, emphysema, active tuberculosis and asthma, spinal anesthesia is often to be preferred. Diabetes and renal disease also may be indications for its use, because this type of anesthesia has little effect on blood sugar and does not irritate the kidneys.

Disadvantages of and Contraindications to Spinal Anesthesia. The untoward effects of spinal anesthesia on the respiration and circulation are its chief disadvantages. The conservative surgeon, therefore, limits the use of spinal anesthesia to operations on the lower abdomen, pelvis and lower extremities. Nausea and vomiting frequently accompany spinal anesthesia but the reason for this is unknown. It is usually precipitated by a sudden movement of the patient or traction on viscera. Motor activity of the gastro-intestinal tract may be greatly enhanced by spinal anesthesia, due to the block of the thoracolumbar sympathetic inhibitory innervation of the bowel (Burstein, 1939). This sometimes is a great inconvenience or even a danger and may contraindicate the use of spinal anesthesia in patients with intestinal obstruction or peritonitis. Atropine and ephedrine may be employed to overcome the enhanced gastro-intestinal activity. Postanesthetic headache is common following spinal anesthesia. It probably results from the loss of spinal fluid through the needle wound of the dura rather than from a direct action of the anesthetic agent.

Patients suffering from hemorrhage or shock respond poorly to spinal anesthesia for reasons mentioned. This type of anesthesia should not be used for patients with hypertension or hypotension. Cerebrospinal disease and the presence of skin infection at the site of injection constitute additional contraindications.

The strongest argument against the routine use of spinal anesthesia is the statistical evidence that general anesthesia is a safer procedure. The incidence of death due to spinal anesthesia is placed at approximately one fatality in 3000 cases, a much higher ratio than for general anesthesia. In accounting for the mortality figures, however, it should be pointed out that the type of patient who receives a spinal anesthetic is often a poor surgical risk.

Preanesthetic Medication. Preanesthetic medication for spinal anesthesia is much the same as for general anesthesia. It is mainly for the purpose of calming the patient, dulling his senses and removing apprehension. The usual routine is to administer a barbiturate the night before and morphine and scopolamine one hour before operation. A short-acting barbiturate may also be given before operation but this is not mandatory as is the case prior to other types of injection anesthesia. Systemic reactions characterized by stimulation of the central nervous system are rare following the intrathecal injection of local anesthetics. Medullary paralysis resulting from the direct access of the anesthetic agent to the region of the medulla is more to be feared. It has been shown by CoTui (1933) that barbiturates increase the susceptibility of the medulla to paralysis by *direct* application of local anesthetics. Small doses of morphine and scopolamine do not have this effect.

Supplementary Anesthesia. Spinal anesthesia is of relatively short duration and if a surgical procedure lasts longer than is anticipated, it may be necessary to administer supplemental anesthesia. Often infiltration anesthesia answers the purpose but on occasions it may be necessary to superimpose general anesthesia. In such an instance, an anesthetic agent which can be given with large amounts of oxygen should be employed, for the tissues of the patient under spinal anesthesia are likely to be slightly anoxic, especially if there is respiratory depression or hypotension. The best general anesthetic to employ is cyclopropane. The intravenous injection of barbiturates should be undertaken with care because of the possible deleterious effects on the blood pressure and respiration.

Choice of Anesthetic Agent. The local anesthetics most commonly employed for spinal anesthesia are procaine, metycaine and nupercaine. Procaine is the safest, least irritating, and by far the most widely used. Its chief disadvantage is its short duration of action, anesthesia lasting about one hour. Some anesthetists use combinations of these agents in order to increase the duration of anesthesia.

Epidural Anesthesia. Epidural anesthesia is an extensive form of block anesthesia produced by injecting a local anesthetic into the epidural space. With this technic sensory anesthesia extending as high as the chin can be produced without seriously affecting respiration or circulation.

Technic. At the foramen magnum the cranial dura splits into two layers. The inner layer becomes the dura of the spinal cord. The external layer forms the periosteal lining of the spinal canal. Between these two layers is the epidural space which contains semiliquid fat and venous plexuses. The epidural space varies in extent, being largest at the level of the second lumbar vertebra where it occupies approximately one-half the diameter of the spinal canal. The spinal nerves traverse this space after the anterior and posterior nerve roots have joined within the subarachnoid space and obtained their dural sheath.

In carrying out an epidural anesthesia, the usual procedure is to enter the space at the level of L_2. The entrance of the needle can be conveniently detected inasmuch as a negative pressure exists in the epidural space and fluid (in a suitable glass indicator) can be seen to be aspirated. The anesthetic solution is then slowly administered.

Several technics of epidural anesthesia have been devised. The following is that of Odom (1936). From 35 to 50 cc of two per cent procaine are necessary for adequate anesthesia. The extent of epidural anesthesia is governed by the volume of fluid injected and the position of the patient. Employing the Trendelenburg position following the injection of 50 cc, anesthesia extends upward to the level of the chin. After smaller volumes and using the Fowler position, however, anesthesia can be limited to the perineal region. If the contemplated surgical procedure is on one side of the midline, the patient should lie on that side to facilitate the gravitation of the anesthetic toward the nerves supplying the area of operation.

Action of Local Anesthetics in the Epidural Space. Epidural anesthesia refers to the site of injection rather than to the site of nerve block. Within the epidural space the spinal nerves are covered with a thick layer of dura and it is not until the nerves leave the intervertebral foramina that this protection is lost. It is likely that after epidural injection the local anesthetic solution diffuses along the perineural lymphatics to leave the epidural space at the intervertebral foramina and block the spinal nerves outside of the spinal canal. Thus the end-result of epidural anesthesia is essentially an extensive paravertebral block.

The diffusion of a local anesthetic along the entire length of the spinal epidural space and out through the many intervertebral foramina is a relatively slow process and for this reason there is an appreciable latent period between the injection and the onset of anesthesia. Usually, within 10 minutes after injection a narrow zone of sensory paralysis is evident in the skin over the lower abdomen which is supplied by nerves originating at the level of injection. This area of anesthesia soon spreads to cover the whole body from the chin to the lower extremities. Surgical anesthesia is obtained in from 15 to 30 minutes. Complete motor paralysis is not observed, for apparently the concentration of anesthetic agent gaining access to the spinal nerves is not sufficient to block the larger and more resistant motor fibers. Sensory block persists for one and one-half to two hours. Despite the fact that motor block is incomplete, abdominal relaxation is adequate due to the interruption on the afferent side of the reflexes controlling muscle tone.

Advantages of Epidural Anesthesia. Epidural anesthesia possesses all the advantages of spinal anesthesia with few of its disadvantages. The anesthetic agent does not have direct access to the medulla or spinal cord, nor does it block the motor nerves of the respiratory muscles. Consequently this type of anesthesia can be used for thoracic as well as for abdominal surgery. Neither is the blood pressure affected as markedly as in spinal anesthesia. Even when sensory block extends to the neck, the blood pressure usually falls no more than 20 to 30 mm. Nausea and vomiting rarely occur during anesthesia and patients are free of postanesthetic headache and urinary retention.

Disadvantages of Epidural Anesthesia. Difficulty in technic probably constitutes the chief disadvantage of epidural anesthesia. If injection is mistakenly made into the subarachnoid space, the amount of anesthetic employed proves toxic. A sensible precaution is slowly to inject the first 10 cc of anesthetic solution and await the effect. If the injection has been made intrathecally, it is soon apparent that spinal anesthesia has been performed. The second major disadvantage is the large amount of drug which must be employed. This averages about one gram of procaine, and systemic reactions may result in sensitive individuals. Reactions may be controlled by the prophylactic administration of a barbiturate. Epinephrine may also be incorporated in the anesthetic solution in order to retard absorption. Because of the possibilities of systemic reactions, procaine is the safest agent to employ, although some anesthetists combine procaine with a local anesthetic having a longer duration of action. Still another disadvantage is the long latent period between the injection and the onset of anesthesia.

Indications. Epidural anesthesia may be employed to advantage when both general and spinal anesthesia are contraindicated. Thus it is of great value in debilitated individuals, in persons suffering from pulmonary disease, renal disease, and diabetes complicated by hypertension, etc. Epidural anesthesia can also be used for surgery in the upper abdomen and thorax.

Miscellaneous Uses of Local Anesthetics. The local anesthetics are often employed under circumstances when a surgical procedure is not the immediate objective but rather when the relief of pain and the abolition of vasomotor and other reflexes attending pain are desired. For example, procaine is of definite value in the treatment of fractures not requiring accurate reduction and immobilization as, for example, those of the lumbar transverse processes, vertebral spinous processes, head of the radius, epicondyle, etc. Ligamentous sprains, muscle contusions or sprains, acute traumatic synovitis, and acute bursitis are also benefited by procaine anesthesia. The use of procaine in the aforementioned conditions has been reviewed by Outland and Hanlon (1940).

SECTION V

DRUGS ACTING ON AUTONOMIC EFFECTOR CELLS

CHAPTER 19

ANATOMICAL, PHYSIOLOGICAL AND GENERAL PHARMACOLOGICAL CONSIDERATIONS

A clear understanding of the anatomy and physiology of the autonomic nervous system is essential to a study of the pharmacology of the *autonomic drugs.** In a real sense, these drugs mimic the effects of nerve stimulation. One can often predict the action of autonomomimetic agents on various organs of the body if the responses manifested to nerve impulses are known.

Many changes have occurred in recent years in our knowledge of the functional organization of the autonomic nervous system and the rôle it assumes in maintaining the economy of the body. Perhaps the most important progress for the pharmacological interpretation of the actions of autonomic drugs has been made in the field of the chemical mediation of nerve impulses. This subject will be discussed in some detail because it has also added to our terminology, revised the distinctions between the parasympathetic and sympathetic nervous systems, reclassified nerve fibers, opened a new field of investigation for striomuscular drugs, and made contributions to therapeutics and to the surgery of the visceral nervous system.

Before discussing the pharmacology of the individual autonomic drugs, certain basic considerations which enable the student better to understand their actions and uses will be presented. These preliminary considerations are divided into three sections—*anatomical, physiological* and *pharmacological.*

ANATOMICAL CONSIDERATIONS

The autonomic nervous system is also called the visceral, vegetative or involuntary nervous system. It consists of nerves, ganglia and plexuses which provide innervation to the heart, blood vessels, glands, viscera and smooth muscles. It is therefore widely distributed throughout the body and controls the so-called automatic or vegetative functions.

Differences Between Autonomic and Somatic Nerves. A major difference between autonomic and somatic nerves is the structures which they innervate. The motor nerves of the involuntary system supply all structures of the body except skeletal muscle, which is innervated by somatic nerves. The most distal synaptic junctions in the autonomic reflex arc occur in ganglia which are entirely outside of the cerebrospinal axis, whereas the synapses of somatic nerves are entirely within the central nervous system. The nerves to skeletal muscles are medullated while the postganglionic vegetative nerves are nonmedullated. When the cerebrospinal nerves are interrupted, the structures they innervate are completely paralyzed, whereas smooth muscles and glands show automatic activity independent of intact innervation. There are, however, certain similarities between these two nervous systems. These will be described later.

---

* The term "autonomic drugs" is sanctioned by long usage rather than by a strict interpretation of the mechanism of action of these drugs. Autonomic drugs act peripherally not on autonomic nerves but directly on muscle and gland cells. More correctly they should be called "drugs acting on autonomic effector cells" but this expression is too cumbersome.

Central Connections of the Autonomic Nervous System. There are two restrictions, incorrect from a physiological standpoint, which are placed upon the anatomical limits of the autonomic nervous system. First, the autonomic nervous system is often erroneously considered as a purely efferent system. Secondly, autonomic nerves and ganglia are too frequently viewed as being entirely peripheral in their organization.

Visceral Afferent Nerves. The afferent nerves coming from visceral structures serve to complete the reflex arcs of the autonomic system. With the exception of the axon reflex, all visceral reflexes are mediated through the central nervous system. The afferent nerves are for the most part medullated fibers and are carried into the cerebrospinal axis by the vagus, pelvic, splanchnic, and other vegetative nerves. For example, about one-half the splanchnic nerve fibers are sensory. Other autonomic afferent fibers are carried in the cerebrospinal nerves from blood vessels in muscles and from certain integumental structures. The cell bodies of these afferent fibers lie in the dorsal root ganglia of the spinal nerves and the sensory ganglia of certain cranial nerves. Their proximal processes enter the spinal cord through the dorsal spinal roots to connect directly or through internuncial neurones with cells lying in the lateral horns. These cells send axones to synapse with other neurones in the autonomic ganglia which lie outside the central nervous system. The ganglion cells are in reality anterior horn cells which have migrated from the developing neural tube. They give origin to the last neuronal link in the reflex arc and their axonal fibers end in the effector organs. A special example of an autonomic afferent system is that arising from the vasosensitive and chemoreceptive endings in the carotid sinus, carotid body and aorta. This system assists in the reflex control of blood pressure, heart rate and respiration, and its afferent fibers pass in the glossopharyngeal and vagus nerves to the medulla.

There are no striking differences between visceral and somatic afferent nerves, and their responses to drugs do not differ. The autonomic drugs do not act specifically on autonomic sensory nerve structures. The clinical importance of these nerves arises especially in connection with the surgical relief of visceral pain. For example, it has been established that pain of cardiac origin is transmitted over the sympathetic and not over the vagal afferent fibers. Relief of pain in certain cases of angina pectoris is therefore obtained by injection of alcohol into or removal of the stellate and upper dorsal sympathetic ganglia.

Central Autonomic Connections. There are extensive central ramifications of the autonomic nervous system above the level of the spinal cord. The integration of the control of blood pressure and respiration in the medulla is well known, but there are higher levels of integration of autonomic functions, especially in the hypothalamus and cortex. For example, the *hypothalamus* helps regulate body temperature, blood sugar, water balance, carbohydrate and fat metabolism, blood pressure and sexual reflexes. Much information concerning central influence on autonomic functions has come not only from physiological studies but also from such clinical syndromes as diabetes insipidus, narcolepsy, hypothermia, hyperthermia and diencephalic autonomic epilepsy. The hypothalamic nuclei which lie posteriorly and laterally are sympathetic in their main connections and their stimulation results in massive discharge of the sympatho-adrenal system. Parasympathetic functions are evidently integrated by the midline nuclei in the region of the tuber and by those lying anteriorly. The supraoptic nuclei are also involved in maintenance of water metabolism through their connections with the posterior lobe of the hypophysis. This hypothalamic-pituitary system represents a centrally located autonomic function the peripheral control of which is hormonal in nature.

The *cortex* provides another suprasegmental level of integration for sympathetic and parasympathetic functions. It is mainly here that the correlation between somatic and vegetative functions occurs, both in the sensory and motor fields. The activities of the cardiovascular, gastro-intestinal and many other systems are partially controlled at this highest level, and the basis for conditioned reflexes and visceral processes connected with mental states rests in these cortical connections. For example, sleep itself appears to be essentially a central and peripheral autonomic integration.

The details of the central autonomic nuclei and their control of the peripheral vegetative system must be sought elsewhere (*see* Fulton, 1938, for an excellent review of this subject). Attention is called to these suprasegmental levels of integration because they are often entirely neglected in discussions of autonomic drugs. The actions of these drugs on central nuclei are poorly understood but may be important in determining the character of the body's response. Likewise, the many visceral effects of drugs which stimulate or depress the central nervous system emphasize the significance of central autonomic integrations.

Divisions of the Peripheral Autonomic System. On the motor side, the autonomic nervous system consists of two large divisions—the *sympathetic* (orthosympathetic) or *thoracolumbar* outflow, and the *parasympathetic* or *craniosacral* outflow. The two divisions are quite distinct in many of their anatomical and physiological characteristics. The differences, however, are not absolute and evidence will be presented in a later section to show that certain revisions must be made in the traditional concept that the two systems are always mutually antagonistic.

Only the briefest outline of those anatomical features necessary for an understanding of the actions of autonomic drugs can be given here. The arrangement of the principal parts of the autonomic nervous system is presented schematically in Figure 31, which may be consulted for further elucidation of the following description.

The Sympathetic Nervous System. The cells of this division lie in lateral horns of the spinal cord and extend from the seventh cervical to the third lumbar segment. The anterior nerve roots carry axones from these cells which synapse with neurones lying in certain ganglia outside the cerebrospinal axis. The sympathetic ganglia comprise three groups—the vertebral, prevertebral and terminal.

The *vertebral* sympathetic ganglia consist of 22 pairs which lie on either side of the vertebral column to form two lateral chains. The ganglia are connected to each other by nerve trunks and to the spinal nerves by rami communicantes. The white rami carry the preganglionic medullated fibers from the spinal cord by way of the anterior spinal roots. The gray rami issue from the ganglia and carry postganglionic fibers back to the spinal nerves for distribution to blood vessels of striate muscle and skin and to sweat glands and pilomotor muscles.

The *prevertebral* ganglia serve as synaptic centers. They lie in the abdomen and pelvis on the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), the superior mesenteric and the hypogastric ganglia. The *terminal* ganglia are few in number, lie near the organs which they innervate and consist especially of those connected with the urinary bladder and rectum.

The classic experiments of Langley (page 488) established the course of sympathetic nerve fibers and the sites of their synapses. In this work he utilized the alkaloid nicotine which prevents the response of ganglion cells to preganglionic nerve stimulation. The postganglionic fibers issuing from the sympathetic ganglia reach all the visceral structure of the thorax, abdomen, head, and neck. The trunk and limbs are supplied by means of the sympathetic fibers in the spinal nerves as described heretofore. The prevertebral ganglia contain the cell bodies whose axones supply the glands and smooth muscle of the abdominal and pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses such as the cardiac, esophageal and pulmonary. The sympathetic distribution to the head and neck is by way of the cervical sympathetic chain and its three sympathetic ganglia. All postganglionic fibers in this chain arise from cell bodies located in these three ganglia. All preganglionic fibers arise from the upper four thoracic segments of the spinal cord. There are no sympathetic fibers leaving the central nervous system above the first thoracic level.

Each preganglionic fiber issuing from the spinal cord synapses only once. This synapse may occur in any of the ganglia mentioned and need not correspond to the original level of issuance from the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the vertebral ganglia without synapsing and form the splanchnic nerves. Most of the splanchnic fibers do not synapse until they reach the celiac ganglion. The nerve fibers going to the adrenal medulla are unique in that, although they are preganglionic, they innervate the gland cells directly. The physiological significance of this apparent anomaly will be discussed later.

Parasympathetic Nervous System. This system consists of three outflows of preganglionic fibers from the central nervous system and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata and the sacral part of the spinal cord.

The *midbrain* or tectal outflow consists of fibers arising from the Edinger-Westphal nucleus of the *third* cranial nerve and going to the ciliary ganglion in the orbit. The *medullary* outflow comprises the parasympathetic components in the seventh, ninth and tenth cranial nerves. The fibers in the *facial* nerve form the chorda tympani which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the Vidian nerve and innervate the sphenopalatine ganglion. The *glossopharyngeal* autonomic components innervate the otic ganglion. From the aforementioned peripheral ganglia, postganglionic parasympathetic fibers originate which supply the sphincter of the iris, the ciliary muscle and the salivary, lacrimal and mucous glands. These fibers also include the vasodilator nerves to the organs mentioned and the remaining structures of the head. The *vagus* nerves arise in the medulla and consist of preganglionic fibers which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. The preganglionic fibers are thus very long, and the postganglionic quite short. The vagus nerve in addition carries many afferent fibers from the viscera into the medulla.

The *sacral* outflow consists of axones which arise from cells in the second, third and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves. They synapse in terminal ganglia lying near the bladder, rectum, and sexual organs.

The vagal and sacral outflows provide motor, secretory and vasodilator fibers to all the thoracic, abdominal and pelvic organs, as can be seen by reference to Figure 31. The functions of these nerves will be described later.

Difference Between Sympathetic and Parasympathetic Nerves. On purely anatomical grounds, the two divisions of the autonomic nervous system differ in several important respects. Chief among these is the fact that *sympathetic fibers* ramify to a much greater extent. A preganglionic sympathetic fiber may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it finally synapses with a postganglionic neurone. Also, it synapses with a large number of postganglionic fibers. In some ganglia, the ratio between preganglionic axones and ganglionic cells may be one to 20 or more. In this manner, a diffuse discharge of the sympathetic system is possible.

The *parasympathetic system,* on the other hand, has its terminal ganglia very near to the organs innervated and thus is more discrete and limited in its discharge of impulses. In some organs, there appears to be a one to one relationship between the number of parasympathetic preganglionic and postganglionic fibers.

Details of Innervation of Effector Organs. The manner in which autonomic nerve endings make contact with the effector cells is of importance for an understanding of the mechanism of action of autonomic drugs. Unfortunately, histological investigation in this field has yielded only fragmentary information. For example, it is highly desirable to know whether each muscle cell is innervated by a nerve fiber. In the intestinal musculature, it appears that only one muscle cell in a hundred receives a nerve ending. Obviously some other method of stimulation than a direct nerve impulse must exist for those cells which are not innervated. The ciliary muscle of the eye, on the other hand, appears to have a nerve fiber for each muscle cell, but the involuntary ocular muscles are peculiar and possess features common to skeletal muscle. Indeed, in some animals (birds) the iris is composed entirely of striped fibers. In the heart muscle there also appears to be a discrepancy between the number of nerve fibers and muscle cells, but the syncytial nature of the myocardial elements apparently compensates for the lack of abundant nerve fibers.

Whether the nerve ending terminates on the surface of the cell or actually enters the protoplasm is of importance for determining the site of action of autonomic drugs. There is evidence of intracytoplasmic nerve endings in both smooth and cardiac muscle, but the nerve endings of gland cells may be on the cell surface (adrenal, gastric, salivary glands) or within the cytoplasm (hepatic cells).

When an organ is innervated by both sympathetic and parasympathetic nerve fibers, the question arises whether each innervated cell receives fibers from both systems. Although this problem is unsettled, there is no histological evidence at present to warrant the conclusion that both nerve divisions are represented in the same effector cell. It would be more consistent with our knowledge of drug action to have sympathetic fibers supplying certain cells and parasympathetic fibers other cells, but this has not yet been established.

PHYSIOLOGICAL CONSIDERATIONS

Certain physiological aspects of the autonomic nervous system are of importance for the understanding of the action of autonomic drugs.

The Response of Effector Organs to Autonomic Impulses. A clear understanding of the responses of various viscera to autonomic nerve impulses makes it possible to anticipate the actions of neuromimetic drugs. In general, the sympathetic and parasympathetic systems stand as physiological antagonists. If one system inhibits a certain function, the other augments that function. Most viscera are innervated by both divisions of the autonomic nervous system, and the level of activity at any one moment is the result of the algebraic sum of the two component influences. The action of one system is brought into relief by removal or paralysis of the opposing system.

The effects of stimulating the sympathetic and parasympathetic nerves to various organs, visceral structures and effector cells are summarized in Table 17.

General Functions of the Autonomic Nervous System. The integrating action of the autonomic nervous system is of the utmost importance for the well-being of the organism. In general, the autonomic nervous system regulates the activities of structures which are not under voluntary control and which as a rule function below the level of consciousness. Thus respiration, circulation, digestion, body temperature, metabolism, sweating, and the secretions of certain endocrine glands are regulated by the autonomic nervous system and its central connections. As Claude Bernard and Cannon have emphasized, the constancy of the internal

TABLE 17

RESPONSES OF EFFECTOR ORGANS TO AUTONOMIC NERVE IMPULSES

	ADRENERGIC IMPULSES *	CHOLINERGIC IMPULSES *
EYE

* The anatomical classes of fibers carrying adrenergic and cholinergic impulses to effector organs are described on page 335.

environment of the organism is to a large extent controlled by the vegetative nervous system. The former investigator used the term *milieu interne* and the latter *homeostasis* to express the concept of the constancy of the internal environment.

The sympathetic and parasympathetic systems, however, have contrasting functions in regulating the internal environment. The *sympatho-adrenal system* is not essential to life, and animals deprived of it can continue a fairly normal existence within the sheltered confines of the laboratory. They grow, become pregnant and give birth to young, although gestation may be abnormal (high incidence of stillbirths), the maternal instinct is absent, and the mammary glands do not secrete. Such animals are also sensitive to cold and their basal metabolic rate is reduced about 10 per cent. They show no tendency toward vagotonia in that the digestive processes are normal, the heart rate is not slowed and the blood pressure is unaltered. Even the peripheral vessels regain a certain degree of intrinsic vasomotor tone. Under circumstances of stress, however, the lack of the sympatho-adrenal functions becomes manifest. In cats, for example, body temperature cannot be regulated when the environment is cold or hot; the blood sugar does not rise in response to urgent need; compensatory vascular responses to hemorrhage, oxygen want, excitement or work do not occur; resistance to fatigue is lessened; instinctive reactions to fright or danger are lost; pilomotor responses are absent, and other serious deficiences in the protective forces of the body are discernible. Dogs, for a number of reasons, withstand complete sympathectomy better than do cats (McDonough, 1939).

The sympatho-adrenal system frequently discharges as a unit and this occurs especially under circumstances of rage and fright (Cannon, 1932). The autonomic structures all over the body are affected at the same time. The heart is accelerated; the blood pressure rises; red blood cells are poured into the circulation from the spleen; the blood redistributes itself from the skin and splanchnic bed to the skeletal muscles; the blood sugar rises; the palpebral fissures widen; the pupils dilate; and, on the whole, the organism is better prepared for fight or flight.

The *parasympathetic system,* on the other hand, is essential to life and is organized for discrete and localized discharge and not for mass responses. It is concerned rather with the functions of conservation and restoration than with the expenditure of energy. It slows the heart, lowers the blood pressure, stimulates the gastro-intestinal movements and secretions, aids absorption, protects the retina from excess light, and empties the bladder and rectum. No useful purpose would be served in the body if the parasympathetic nerves all discharged at once. Indeed, such an event would be harmful.

Cannon (1932) has aptly summarized the distinctions between the two systems as follows, "The sympathetics are like the loud and soft pedals, modulating all the notes together; the cranial and sacral innervations are like the separate keys."

Chemical Mediation of Nerve Impulses

Before proceeding further with physiological considerations, it is necessary to describe certain basic changes that have occurred in our knowledge of the mediation to effector organs of the excitatory process initiated by nerve impulses. This newer information is collectively referred to as the theory of the *"chemical transmission of nerve impulses,"* or *"neurohumoralism."* The theory holds that nerve impulses effect responses in muscles and glands through liberation of a chemical substance which acts as the major local exciting agent. The theory will be outlined in some detail because it has profoundly affected our knowledge of the mechanism and site of action of autonomic drugs.

Historical. The first reference to the possibility that chemical substances might be concerned in the transmission of the excitatory process to effector cells was probably made by Dubois-Reymond who, in 1877, stated that transmission of the nerve impulse may be produced either electrically by action currents or chemically by exciting substances like ammonia or lactic acid formed at the surface of nerve endings. In 1904, T. R. Elliot, while a student of physiology at Cambridge, England, postulated that sympathetic nerve impulses released tiny amounts of an epinephrine-like substance in immediate contact with effector cells. He considered this substance to be the chemical step in the process of stimulation. Elliot's evidence was meager and he was led to this theory by the similarity between the effects of stimulation of sympathetic nerves and the injection of epinephrine. He was also influenced by the fact that long after sympathetic nerves degenerated the effector organs still responded characteristically to the hormone of the adrenal medulla. In 1905, Langely suggested that effector cells have both excitatory and inhibitory "receptive substances," and that the response to epinephrine depended on which type of substance was present.

In 1906, Dixon was so impressed by the correspondence between the effects of the alkaloid muscarine and the responses to vagal stimulation that he advanced the important idea that the vagus nerve liberated a muscarine-like substance which acted as a chemical transmitter of its impulses. Dixon concluded from experimental data that "excitation of a nerve induces the local liberation of a hormone which causes specific activity by combination with some constituent of the end-organ, muscle or gland." Dixon's theory met with universal skepticism which discouraged him from following this promising field of investigation.

In the year that Dixon advanced the above hypothesis, Reid Hunt announced his studies on acetylcholine and other choline esters. In 1914, Dale thoroughly reinvestigated the pharmacological properties of acetylcholine. He was so impressed with the remarkable fidelity with which this drug reproduced the responses to stimulation of parasympathetic nerves that he introduced the term "parasympathomimetic" to characterize its effects. Dale also noted the brief duration of the action of this chemical and believed that an esterase in the tissues rapidly splits acetylcholine to acetic acid and choline, the latter being a much less potent compound.

The Vagus-Substance (Parasympathin). The brilliant researches of Otto Loewi, which were begun in 1921, established the first real proof of the chemical mediation of nerve impulses by the peripheral release of specific chemical agents. Loewi's studies will be described because they are often quoted and the technic he employed is basic to investigations in this field. He stimulated the vagus nerve of a perfused (donor) frog heart and allowed the perfusion fluid to come in contact with a second (recipient) frog heart used as a test object. He noted that a substance was liberated from the first organ which slowed the rate of the second. Loewi called this chemical substance "vagus-substance" (parasympathin). He also discovered that an accelerator substance similar to epinephrine was liberated into the perfusion fluid when the action of the sympathetic fibers in the frog's vagus predominated over the inhibitory fibers.

Loewi's observations were not immediately corroborated by other investigators because of certain technical difficulties. The cardiac nerves from the vagus in frogs also contain the sympathetic accelerator component—the accelerans. The nerve is a mixed one, therefore, and its stimulation at times causes inhibition and at other times acceleration. The particular result varies with the frog and with the season of the year. In winter, inhibition predominates; in summer, acceleration. The exact opposite holds true for the toad. Loewi's discoveries were eventually confirmed and are now universally accepted. The essential features of the experiments are shown in Figure 27 which illustrates Bain's (1932) modification of Loewi's technic.

It was necessary to show that the aforementioned observations also held true for warm-blooded animals with more highly organized nervous systems. In 1927,

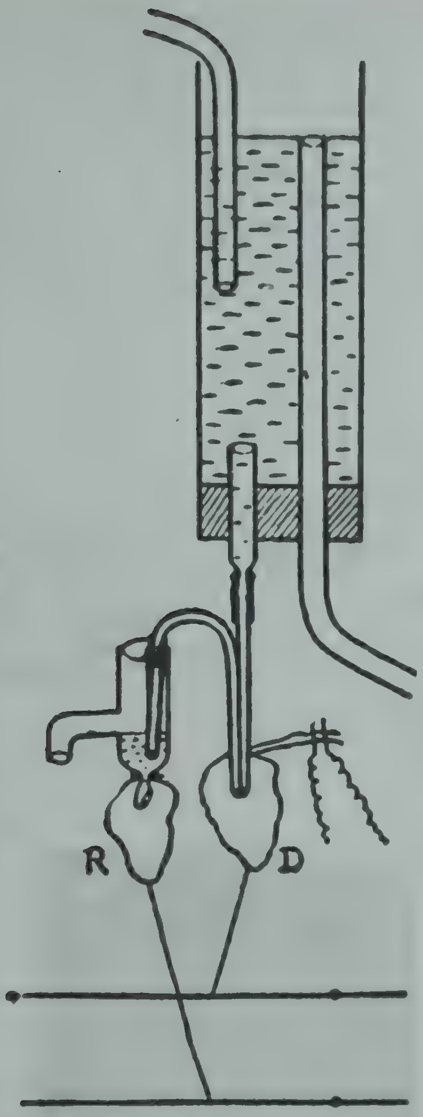

FIGURE 27. *Bain's modification of Loewi's technic for demonstrating the release of the "vagus-substance" upon stimulation of the cardiac nerve to the frog's heart.*

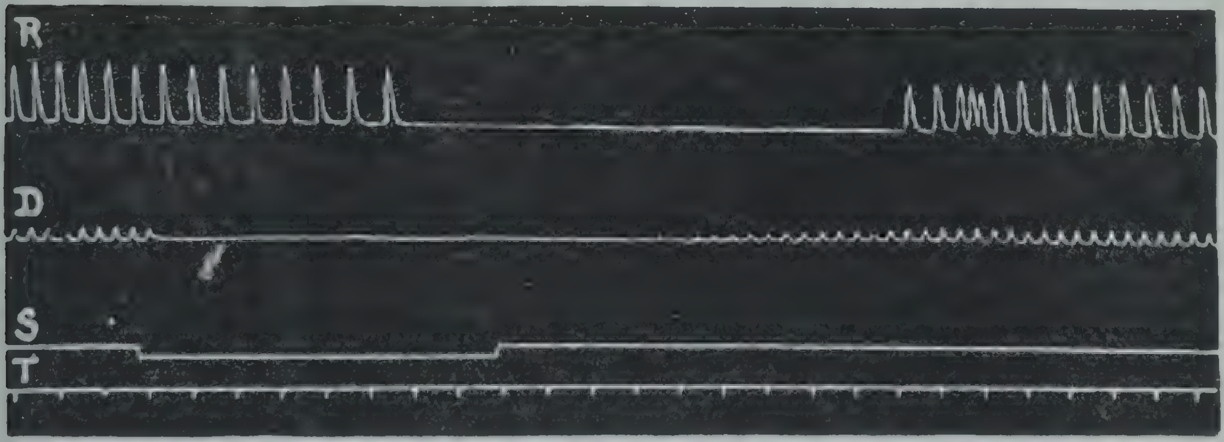
The donor heart (*D*) with nerves intact is perfused at constant pressure with a balanced salt solution. The perfusion fluid then passes to the isolated recipient heart (*R*). Cardiac contractions are recorded by means of writing levers; time (*T*), in five second intervals. The vagus fibers to the donor heart are stimulated (*S*) for 40 seconds, and the donor heart is arrested. Slowing of the recipient heart is apparent within fifteen seconds after arrest of the donor heart and asystole occurs shortly thereafter. (After Bain, 1932. Courtesy of the *Quarterly Journal of Experimental Physiology* and Sir Edward Sharpey Schafer's Trustees.)



Rylant duplicated Loewi's frog experiments using perfused rabbits' hearts. Feldberg and Krayer (1933) extended the field by using intact cats and dogs. They stimulated the cardiac vagus and were able to detect the liberation of the vagus-substance by its effects on eserinized leech muscle and the blood pressure of cats (Figure 28). They presented strong evidence to indicate that the vagus-substance is acetylcholine.

Many other investigations established quite conclusively that a chemical mediator was instrumental in the transmission of excitation not only to the heart but also to other parasympathetically innervated structures. The experiments of Dale and Feldberg (1934) demonstrated the presence of the vagus-substance in the eserinized perfusion fluid collected from the stomach of a dog whose vagi had been stimulated. Similar experiments have demonstrated the chemical transmission of parasympathetic nerve impulses to the small intestine (Bunting, Meek and Maaske, 1935) and to the salivary glands (Babkin and associates, 1932). For example, stimulation of the chorda tympani imparts to the perfusion fluid flowing through the submaxillary gland the power to depress blood pressure, inhibit heart rate, stimulate peristalsis and excite salivary secretion. The work of Engelhart (1931) is of special significance because it shows that the physiological stimulation of nerves also produces the chemical mediator. He demonstrated that impulses over the short ciliary nerves, produced either by electrical stimulation or reflexly by exposure of

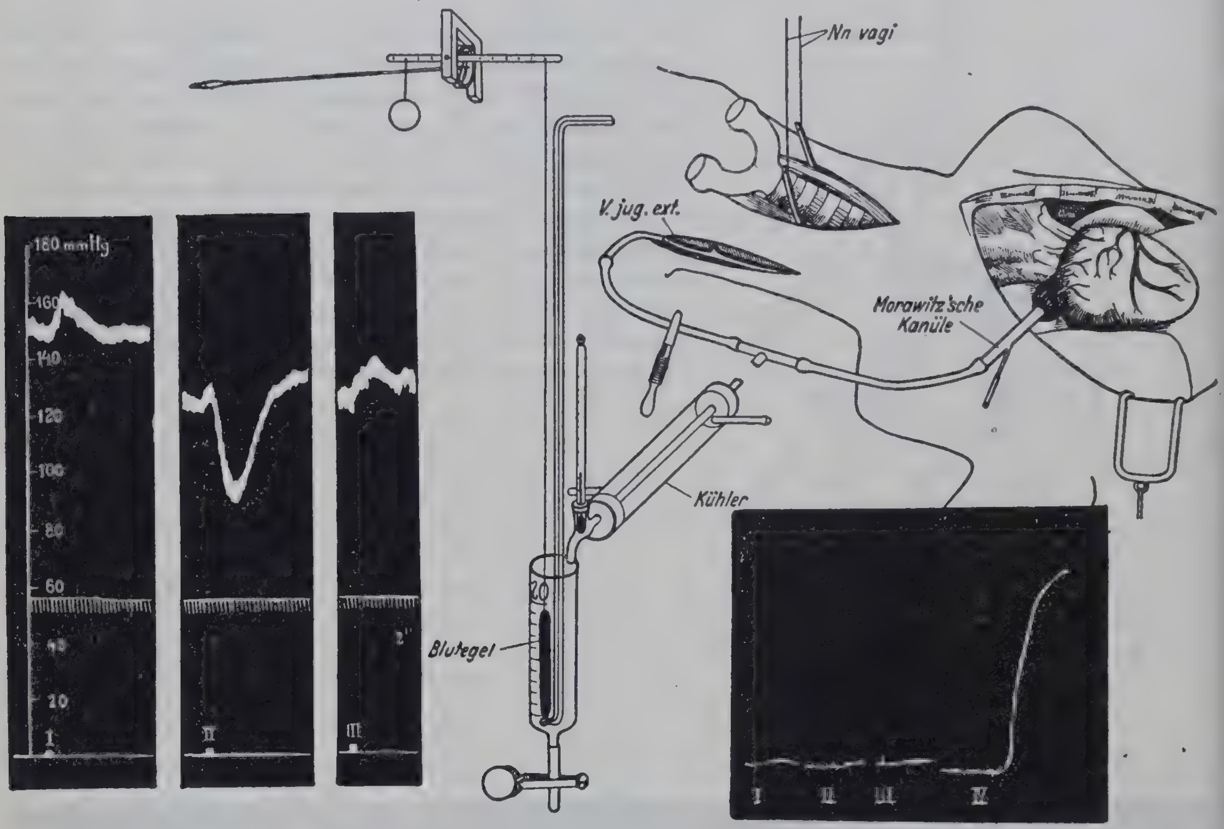


FIGURE 28. *Demonstration of the release of the vagus substance (acetylcholine) in the mammalian heart.*

Schematic representation of exposed dog's heart, vagus nerves and external jugular vein. A Morawitz cannula is inserted into the coronary sinus, from which blood can be diverted at will into a cooling chamber preparatory to testing it on the sensitized leech muscle for its content of acetylcholine. The lower right hand tracings represent responses of the leech muscle to coronary blood obtained under the following circumstances: I, control; II, during vagus stimulation; III, control after eserinization of the dog; IV, during vagal stimulation after eserinization. The carotid blood pressure tracing on the left is that of a cat injected with samples of the dog's coronary blood taken as follows: I, control after eserinization of the dog; II, during vagal stimulation after eserinization. The cat was then atropinized and at III is shown the absence of the vasodepressor response to the same sample of blood used at II. Note that only when the chemical mediator of the vagal impulses is protected by eserine from enzymatic destruction is it possible to demonstrate its presence by the use of appropriate test objects. (After Feldberg and Krayer, 1933. Courtesy of the *Archiv für experimentelle Pathologie und Pharmakologie.*)

the retina to light, liberated a substance which imparted to the aqueous humor the pharmacological properties of acetylcholine. The evidence is overwhelming that stimulation of craniosacral autonomic nerves to muscles and glands results in the release of a chemical which possesses parasympathomimetic properties.

Identification of Acetylcholine as the Vagus-Substance. It is now necessary to digress in order to examine the evidence that the parasympathetic mediator is acetylcholine and to enumerate the pharmacological tests available for detecting its presence in biological fluids.

Acetylcholine can be recognized by a number of fairly specific reactions. The common physiological indicators of its presence and their sensitivity in micrograms per liter (0.001 mgm per liter; 1:1,000,000,000) are given in the following table compiled by Gaddum (1936):

Leech muscle (isolated and treated with eserine)	2
Rabbit auricle (isolated and treated with eserine)	4
Frog heart (Straub method)	10
Mouse intestine	10
Rabbit intestine	20
Frog's rectus abdominis (isolated and eserinized)	20
Cat's denervated gastrocnemius	100

Inasmuch as none of the tests is absolutely specific, certain other criteria must be met in order to establish the identity of the mediator as acetylcholine. These are as follows (Chang and Gaddum, 1933): (1) Eserinization of the test object usually increases the response obtained. (2) The presence of blood or tissue extract decreases or destroys the activity of acetylcholine, and this destruction is prevented by eserine. (3) Acetylcholine is quickly destroyed by hydrolysis in an alkaline medium. (4) Boiling for several minutes in weakly acid solution does not destroy acetylcholine. (5) Atropine, curare and nicotine each block certain definite actions of acetylcholine. (6) The responses to acetylcholine of the various muscle indicators listed bear a definite quantitative relation to each other, and the chemical mediator being studied must give these same relative values before it can be accepted as acetylcholine.

The parasympathetic mediator has fulfilled all the requirements mentioned. Still other reasons for identifying it as acetylcholine (Witanowski, 1925) are that both are dialyzable, soluble in alcohol and not in ether, rendered inactive by an enzyme in blood and tissues (cholinesterase), and restored to activity by acetylation. Also, acetylcholine is the only choline ester that has thus far been chemically identified in animal tissue.

It is believed at present that acetylcholine exists in the tissues in a form which is physiologically inactive, nondiffusible, and insusceptible of destruction by cholinesterase. It would appear that the auricle of the heart, for example, contains more than sufficient acetylcholine to cause cardiac arrest if it were all suddenly changed to an active state. It is of interest that the auricle contains more acetylcholine (and cholinesterase) than does the ventricle, and this may be correlated with the fact that the vagus is distributed mainly to the auricle in the mammalian heart. The change of acetylcholine from an inactive to an active and diffusible form is accomplished by nerve impulses, and it is then susceptible to hydrolytic inactivation by cholinesterase. Nondiffusible tissue acetylcholine persists as long as the parasympathetic nerves remain intact. The ciliary body of the eye, for example, is rich in this substance, but when the ciliary nerve is cut the acetylcholine disappears coincidently with nerve degeneration.

Cholinesterase. The blood and tissues of the body contain a specific enzyme called *cholinesterase* which splits acetylcholine to choline and acetic acid. The choline formed is pharmacologically weak when compared with acetylcholine, having, for example, only 1/100,000 of the vasodepressor potency of its precursor. Cholinesterase appears to exist in tissues especially where acetylcholine is liberated by nerve impulses. The action of the enzyme is rapid and therefore the effect of acetylcholine released by nerve impulses is brief in duration. When cholinesterase is inactivated, however, the action of acetylcholine is prolonged and intensified.

Physostigmine (eserine) and its congeners in low concentration inactivate cholinesterase, and this is the basis for their parasympathomimetic effects. The action of physostigmine on cholinesterase is not one of destruction but merely temporary inactivation, the drug itself being an ester which combines with the enzyme and is slowly hydrolyzed by it. The esterase has all the characteristics of a ferment, and is destroyed by heat at 56 C. and by ultraviolet irradiation.

Attempts have been made to correlate the concentration of serum cholinesterase with various pathological conditions and especially with skeletal muscular dystrophies. No specific disease, as far as can be determined, is characterized by an abnormal concentration of serum cholinesterase, and the only known way markedly to alter the *in vivo* activity of this enzyme is to administer drugs, especially physostigmine and related chemicals.

As will be more fully pointed out when the rôle of acetylcholine in the transmission of the excitatory process in autonomic synapses and neuromuscular junctions is presented, a major criticism which the chemical mediation theory must answer is how acetylcholine released by the nerve impulse is rapidly removed within the brief refractory period of ganglia and skeletal muscles. That cholinesterase exists in tissues in concentrations sufficiently high to destroy the liberated acetylcholine within the refractory period has been shown by the interesting experiments of Nachmansohn and Marnay. In skeletal muscle, the concentration of cholinesterase is several thousand times higher at the motor end plates than in the muscle fibers and the esterasic power of muscle varies directly with its richness of motor end plates (Marnay and Nachmansohn, 1937, 1938). It was calculated by these investigators that 0.000002 μg or 8×10^9 molecules of acetylcholine could be destroyed in five milliseconds by the enzyme present at a single motor nerve ending in a frog's sartorius muscle, and they came to the conclusion that the amount which can stimulate the muscle could easily be destroyed during the refractory period. Later, these observations were extended to the skeletal muscle of the guinea pig, where similar results were obtained. Nachmansohn (1939) also investigated young chickens and mammals (rats and rabbits) and found that the relative richness of embryonic muscle in cholinesterase is associated with the plenitude of nerve elements and almost complete development of end-plates in this tissue. Nachmansohn (1938, 1939) likewise found that a remarkable relationship exists between the amount of acetylcholine which can be split by cholinesterase during the refractory period of effector organs and the amount of acetylcholine liberated by a maximal shock. For example, the enzyme is concentrated in autonomic ganglia (superior cervical) in an amount calculated to be capable of hydrolyzing 2×10^{12} molecules of acetylcholine in one millisecond, or more than sufficient to destroy, within the refractory period of the ganglion, the acetylcholine reported to be liberated by a maximal preganglionic stimulus and capable of causing a postganglionic discharge.

The esterase is much more abundant in the gray matter of the central nervous system than in the white matter. This presumably is due to the presence of cells and synapses in the gray matter. Although the esterasic power varies in different species and in different parts of the cerebrospinal axis, Nachmansohn found it to be quite constant for any one region in any one species. He also noted that the time of appearance of a high concentration of esterase in the embryonic nervous system agreed with the time of the appearance of synaptic function. He suggests that cholinesterase may serve the same function in central synaptic transmission as it does peripherally in ganglia and neuromuscular junctions, that is, the rapid removal during the refractory period of the liberated acetylcholine.

The physiological significance of cholinesterase has been summarized in a review by Nachmansohn (1940).

Sympathin. It has already been stated that Loewi detected an accelerator substance released from frog hearts when the accelerans nerve was stimulated. In the same year, Cannon and Uridil (1921) noted the release from the liver of an epinephrine-like substance upon stimulation of the sympathetic hepatic nerves. This substance increased the blood pressure and heart rate but did not dilate the pupil. Subsequent experiments, mainly by Cannon and his coworkers but also by others, have definitely established that this substance is the chemical mediator of the excitatory process initiated by sympathetic nerve impulses in neuroeffector junctions. The mediator has been called "sympathin" by Cannon in order to avoid premature implications regarding its exact chemistry.

Just as there are biological indicators for the presence of acetylcholine, so also there are specific test objects for detecting sympathin. The test objects are denervated effector organs, and the responses consist of acceleration of the heart rate, elevation of blood pressure, erection of the hairs, inhibition of intestinal musculature, relaxation of the non-pregnant cat uterus, stimulation of the retractor penis, decrease in size of the spleen, and retraction of the nictitating membrane of the cat.

With the use of these tests, it has been repeatedly demonstrated that when sympathetic nerves, with a few exceptions to be mentioned later, are stimulated there is released a chemical substance which has sympathomimetic properties. For example, Rylant (1927) extended Loewi's amphibian observations to rabbit hearts. Again, Bacq (1931, 1933) found that stimulation of the cervical sympathetic nerves caused sympathin to appear in the aqueous humor of the eye. Sympathin is not only liberated under experimental circumstances but is also produced in the intact animal, as during struggle or excitement. It is likewise formed during sham-rage in decorticate animals. The numerous other experiments of this nature and the progressive steps by which Cannon and his associates developed the concept of sympathin can be found in the reviews of this subject (Cannon and Rosenblueth, 1937; Rosenblueth, 1937).

The Nature of the Sympathetic Mediator: Sympathin E and I. In many of its pharmacological properties and perhaps also in chemical structure, sympathin bears close resemblance to epinephrine. Both epinephrine and sympathin are enhanced in their activity by cocaine and by nerve degeneration. Both substances are inactivated by exposure to air for twenty-four hours, by boiling, by strong alkali, and by eosine and ultraviolet light. Both give the same color reactions (Viale color reaction, and green fluorescence with strong alkali and oxygen), the same qualitative ultraviolet absorption spectra of the polyphenols, and show similar variations in absorption as the pH is changed.

Sympathin, however, differs from epinephrine in certain important respects. Epinephrine has both excitatory and inhibitory effects when injected into the body. Thus it accelerates the heart but inhibits the intestine. Sympathin, in contrast, has these two actions, but they are separable. For example, stimulation of a sympathetic nerve supplying a region where there are structures both excited and inhibited by sympathetic impulses produces sympathin which possesses both augmentative and inhibitory properties. When nerves causing only excitatory responses are stimulated, the sympathin released possesses only augmentative activity. This excitatory form of sympathin also differs from epinephrine in failing to stimulate the dilator muscle of the iris. Perhaps the greatest contrast between sympathin and epinephrine is seen in their action after ergotoxine. Whereas ergotoxine blocks the rise of blood pressure produced by epinephrine, it does not prevent that caused by sympathin.

These facts led Cannon and Rosenblueth (1933) to postulate the existence of two forms of sympathin known as sympathin E (excitatory) and sympathin I (inhibitory). The theory holds that a chemical mediator (M) is released at sympathetic nerve endings and combines in effector cells with a hypothetical substance (H). The nature of the H substance depends upon whether the effector cell is excited (E) or inhibited (I) by nerve impulses. It is the combination of M and H which causes the characteristic response of the effector cell, and the MH can therefore be of two varieties, ME and MI. The sympathin released into the blood stream from the effector cell bears the characteristics of this MH combination. If the effector cell was inhibited by nerve stimulation, the sympathin will be inhibitory in nature and is called sympathin I. If the effector cell was excited, the sympathin coming away from it will cause excitation and is called sympathin E. Thus, sympathin E would be formed in the heart and blood vessels, and sympathin I in the intestine, urinary bladder, bronchi, etc. (Figure 29).

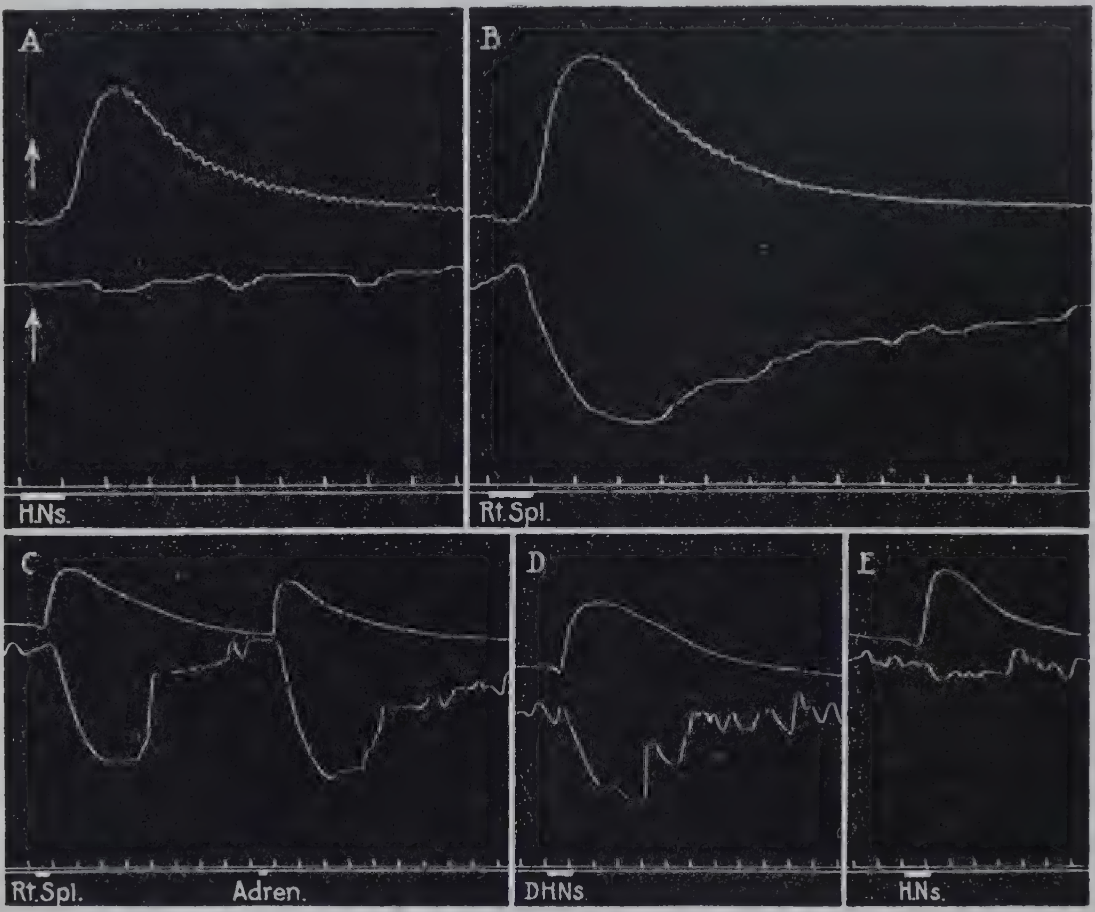

FIGURE 29. *Effects of sympathin from excited* (E) *and inhibited* (I) *sources in the cat on indicators which contract or relax.*

In each instance the upper record is that of the nictitating membrane with cervical sympathetic nerve cut (indicator for sympathin *E*); the lower record, that of the denervated nonpregnant uterus (indicator for sympathin *I*). Direction of arrows indicates contraction. Time is given in half-minutes. *A.* Effects of stimulating the hepatic nerves (*H. Ns.*), purely excitatory. *B.* Effects of stimulating the right splanchnic nerves (adrenals excluded), excitatory and inhibitory. *C.* Effects of stimulating the splanchnic nerves (adrenals excluded) are similar to those of injecting epinephrine (0.3 cc of 1:200,000). *D.* Effects of stimulating the duodenohepatic nerves (*D. H. Ns.*), excitatory and inhibitory. *E.* After severance of the duodenal nerves (excitatory and inhibitory), stimulation of the hepatic nerves (*H. Ns.*), excitatory only. (After Cannon and Rosenblueth, 1933.)

There have been many objections to and modifications of the theory of two sympathins, and these have been reviewed by Cannon and Rosenblueth (1937). For example, sympathin I has not yet been shown to exist alone, but this is probably due to the fact that there is no organ in the body inhibited by sympathetic impulses which does not also contain some excitatory fibers to blood vessels. It has been suggested that the two sympathins are only chemical modifications of epinephrine and are not produced as such in the effector cells. Despite the many criticisms and objections, it seems that no other explanation so well fits all the experimental observations.

Acetylcholine as the Transmitter of Impulses of Certain Postganglionic "Sympathetic" Fibers. It has long been known that the responses to drugs of sweat glands and certain vascular beds (especially in the skin of the face) presented unexplainable anomalies. The sweat glands are innervated by nerve fibers which belong anatomically to the postganglionic sympathetic system, but their function is nevertheless modified by parasympathetic drugs. A similar situation holds true for blood vessels in certain cutaneous areas, although here there is evidence that the vasomotor nerves may be posterior root fibers and anatomically related to the parasympathetic system (*see* discussion by Fulton, 1938). Dale and Feldberg (1934) have demonstrated that nerve impulses which cause vasodilatation and sweating are mediated by acetylcholine and that the nerves involved are functionally analogous to parasympathetic postganglionic nerves. The mechanism of action of autonomic drugs on sweat glands and blood vessels is considerably clarified by this interpretation.

Chemical Mediation in Autonomic Ganglia. The concept of transmission of the excitatory state initiated by nerve impulses in smooth muscle and gland cells by chemical mediators has been extended from the domain of peripheral autonomic effector organs to embrace the autonomic ganglia. The theory holds that the excitation of the ganglion cells is accomplished by the release of a chemical agent when the preganglionic nerve impulse reaches the synapse. The chemical mediator has been identified as acetylcholine. Although the evidence supporting this view has been obtained from sympathetic ganglia, due to their more ready anatomical accessibility, there are many collateral data to suggest that the same mediator is operative in parasympathetic ganglia. In its simplest form, therefore, the theory holds that all preganglionic nerve impulses, whether sympathetic or parasympathetic, stimulate ganglionic cells through the intervention of acetylcholine released at the synapse.

The aforementioned theory is called the Kibjakow-Feldberg theory of ganglionic chemical transmission, after the investigators who were the first to present evidence in this field (Kibjakow, 1933; Feldberg and Gaddum, 1934; Feldberg and Vartiainen, 1934). In brief, the experiments are based on isolating and perfusing a sympathetic ganglion (usually the superior cervical) and testing the perfusate for acetylcholine after stimulation of the preganglionic fibers. According to a number of investigators (*see* MacIntosh, 1939), the mediator appears in the perfusion fluid only after preganglionic and not after antidromic stimulation, and is not liberated spontaneously in the absence of preganglionic stimulation. The ganglionic cells can be discharged by injecting small amounts of acetylcholine into the perfusion fluid or blood supply to the ganglion. The potentiative action of physostigmine on preganglionic stimuli, as shown by Rosenblueth and Simeone (1938), also supports the view that acetylcholine is the transmitter.

Experiments of several types indicate that the ability of preganglionic impulses to discharge ganglion cells and to release acetylcholine into ganglionic perfusates go hand in hand. For example, Kahlson and MacIntosh (1939) have demonstrated that when Locke's solution without glucose is perfused through a sympathetic ganglion, continued stimulation of the preganglionic nerve rapidly exhausts the mechanism of synaptic transmission. The output of acetylcholine from the ganglion simultaneously fails. Both are restored at the same time when glucose, lactate or pyruvate is added to the perfusion fluid. When Locke's solution lacks calcium, Harvey and MacIntosh (1940) have shown that the ganglion cells become more excitable especially to potassium ions, but that synaptic transmission and the release of acetylcholine by preganglionic nerve impulses fail together. Both are promptly and simultaneously restored by adding calcium to the perfusion fluid. Also, MacIntosh (1938) found that after preganglionic nerve section, synaptic transmission and the release of acetylcholine by preganglionic nerve impulses disappeared together, at a time when conduction is still unimpaired in the cut fiber. Collateral evidence of a major or important adjuvant action of acetylcholine in synaptic transmission in ganglia has also been presented by Bronk and associates from a study of the effects on postganglionic nerve responses obtained by perfusing ganglia with low concentrations of acetylcholine (*see* Bronk, 1939). Impressive evidence therefore exists to suggest that acetylcholine, released at ganglionic synapses by preganglionic nerve impulses, plays an important rôle in the transmission of the excitatory process to ganglion cells.

Chemical Mediation of Impulses Causing Secretion of Epinephrine. The cells of the adrenal medulla are innervated through the splanchnic nerves by preganglionic sympathetic fibers coming directly from the central nervous system (Figure 31). Ordinarily, peripheral autonomic structures are not innervated by preganglionic fibers. The anomaly of the adrenal medulla, however, is explainable on an embryological basis, because the cells which secrete epinephrine are modified neuroblasts and are anatomically homologous with sympathetic ganglion cells. Therefore the splanchnic innervation of the adrenal medulla is characteristic of that of an autonomic ganglion. Acetylcholine is thus the mediator of nerve impulses causing the secretion of epinephrine. When the splanchnic nerves are stimulated in an eserinized animal, it is possible to detect acetylcholine as well as epinephrine in the venous blood coming from the gland. Furthermore, acetylcholine is a powerful direct stimulant of the secretion of epinephrine.

Chemical Mediation in Skeletal Muscle. One of the most provocative and significant advances in the field of chemical transmission of nerve impulses has been the demonstration that motor impulses of somatic nerves to skeletal muscles mediate their effects by means of acetylcholine. Thus acetylcholine may not be confined to the autonomic system alone and, if such is the case, some of the traditional differences between the autonomic and somatic nervous systems become less rigid. Dale, Feldberg, Brown and their collaborators have demonstrated that when the motor nerve to skeletal muscle is stimulated under proper experimental conditions acetylcholine can be recovered from the perfusion fluid (Figure 30). The injection of as little as two micrograms of acetylcholine into the artery of a muscle properly prepared and isolated will cause a quick twitch-like contraction which reproduces in many details the type of response obtained from electrical stimulation of motor nerves.

The action of physostigmine on this response as well as the effect of denervation (page 344) are compatible with the theory of chemical mediation in skeletal muscle. Curarine annuls the response of skeletal muscle to injected acetylcholine and to nerve impulses simultaneously without affecting the response to potassium ions or interfering with the release of acetylcholine by the motor nerve impulses (Dale, Feldberg and Vogt, 1936; Brown, Dale and Feldberg, 1936). Buchtal and Lindhard (1939) confirmed these observations by applying curarine under microscopic control directly to the motor end-plate of a lizard's muscle fiber. They noted that the muscle cell simultaneously became insensitive to motor nerve impulses and to the application of acetylcholine, but that the end-plate remained excitable to direct electrical stimulation and to potassium ions, both of which were still normally effective in eliciting a contraction of the muscle fiber.

Although many details of this complex problem require elucidation, it would appear that minute amounts of acetylcholine are liberated at motor nerve endings in skeletal muscle, are concerned with the transmission of the excitatory process across the neuromuscular junction, and initiate the changes which result in muscular contraction (Dale, 1939).

Temporal and Quantitative Aspects of Chemical Transmission in Autonomic Ganglia and Skeletal Muscles. One of the main objections to the theory of chemical transmission of the excitatory process in autonomic ganglia and skeletal mus-

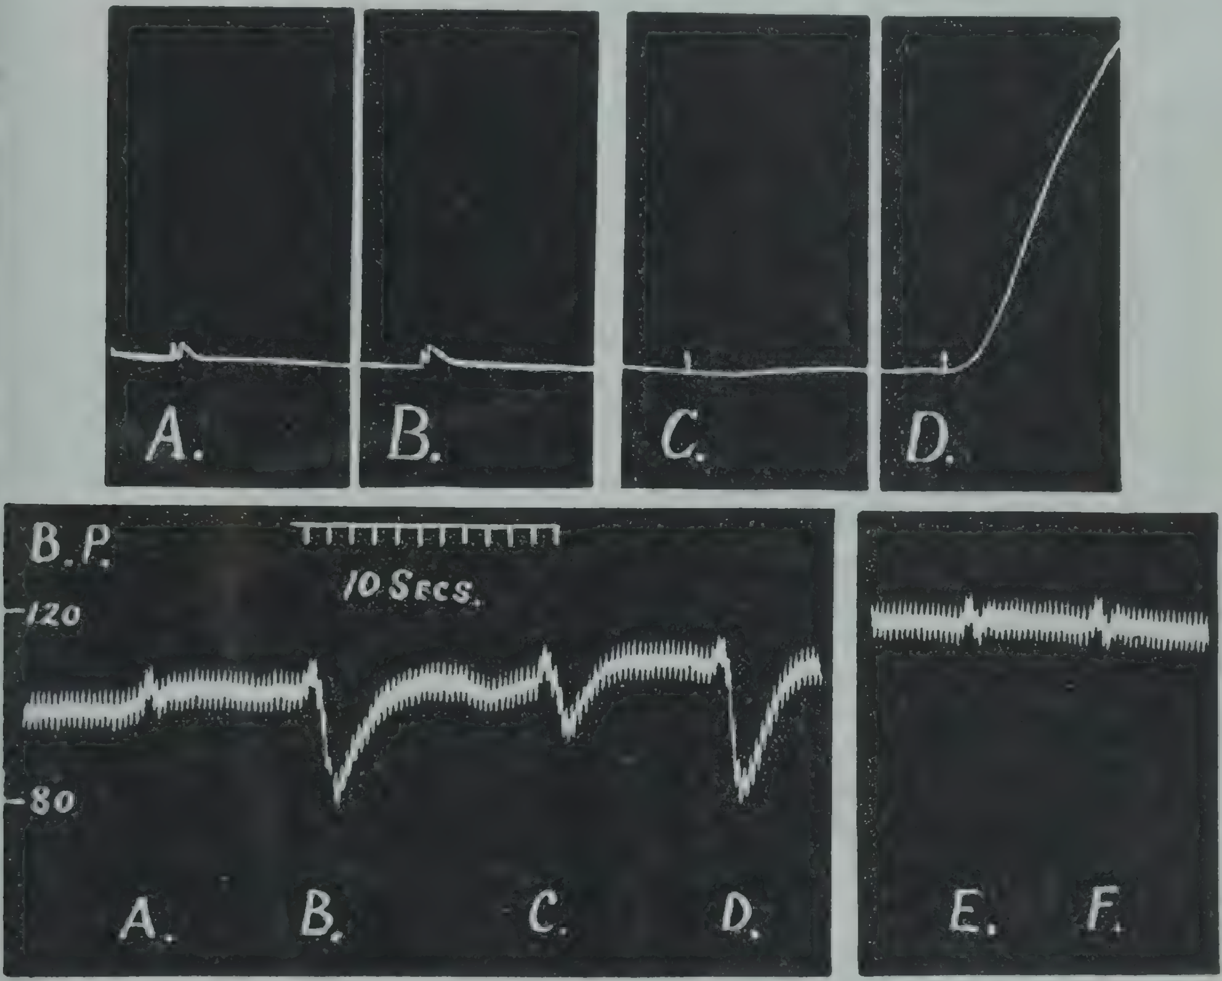

Figure 30. *Acetylcholine as the mediator of motor nerve impulses to skeletal muscles.*

Above: Responses of the sensitized leech muscle to diluted eserinized venous fluid obtained from perfusion of the cat's gastrocnemius muscles. *A.* Control fluid from resting denervated muscle. *B.* Fluid obtained while the muscle was contracting vigorously in response to direct electrical stimulation. In neither case was a contraction of the leech muscle observed, the small rise in the curve being an accidental mechanical effect. *C.* Control fluid from normally innervated muscle. *D.* Fluid obtained during stimulation of the motor nerve to the muscle.

Below: Response of the carotid blood pressure of a cat to venous fluids obtained from the perfused tongue of an eserinized donor cat under curare. *A.* Control fluid obtained before stimulation of the hypoglossal nerve. *B.* Fluid obtained during motor nerve stimulation. *C.* and *D.* Injection of two cc of acetylcholine in dilutions of 1 in 2 x 10^8 and 1 in 10^8, respectively. *E* and *F.* Same as *B* and *D,* after atropinization of the test cat.

Observe that the presence of the chemical mediator of the motor nerve impulses to skeletal muscles can be demonstrated by the responses of suitable test objects when eserine is employed to protect the mediator from destruction, that it is produced only in innervated muscles during stimulation of motor nerves, and that curare does not prevent its release. (After Dale, Feldberg and Vogt, 1936. Courtesy of the *Journal of Physiology.*)

cles has come from the fact that it is necessary to account for the time relations between nerve stimulation and cell response if the mediator is a chemical substance. In the case of peripheral autonomic effector cells, such as the response of the heart or intestine to vagal stimulation, the delay between stimulation and reaction is sufficiently long to be compatible with the theory of chemical transmission. In the case of the heart, for example, the lag may amount to 100 milliseconds which provides ample time for the liberation, diffusion, action and destruction of a chemical mediator. Even the persistence of effects after cessation of stimulation can be accounted for in this way. In ganglia, however, the very short synaptic delay is two milliseconds or less. This would necessitate that acetylcholine be released in minute yet effective amounts and be destroyed almost immediately with "flash-like suddenness," as Dale has expressed it.

The objections to the chemical mediation theory as applied to ganglia have been well reviewed by Eccles (1936, 1937). It is claimed by some workers that there are two types of mediators of nerve impulses—the slow (chemical) and the rapid (electrical). They contend that transmission in ganglia requires the rapid type and that chemical transmitters are concerned only with certain but not all aspects of smooth muscle stimulation. Many of the characteristics and problems of synaptic transmission have been reviewed in a symposium on the synapse by Bronk (1939), Erlanger (1939), Forbes (1939) and Lorente de Nó (1939).

Despite the objections enumerated, the data in favor of the chemical theory, though not complete, are impressive. The evidence for chemical transmission in ganglia is probably as strong as, or stronger than that available for the transmission by acetylcholine of nerve impulses to peripheral effector cells (Brown, 1937). There are several lines of indirect evidence which support the chemical theory as applied to ganglia. These have to do with regeneration of cross-sutured nerves (page 335), the action of potassium salts, nicotine, eserine and other drugs on ganglia (page 331), sensitization of ganglia to acetylcholine after degeneration of preganglionic fibers (page 344), and the responses of skeletal muscles to drugs (page 341). Nevertheless, further information concerning the quantitative and temporal features of acetylcholine-cholinesterase relationships in biological systems is urgently required. The promising investigations of Nachmansohn already described suggest that the esterase concentrations at neuro-effector junctions are sufficiently high to destroy, within the refractory period of the effector cells, amounts of acetylcholine which have stimulating effects. More data of this type are necessary.

Chemical Mediation of Central Synaptic Transmission. A number of workers who most vigorously support the acetylcholine theory of chemical transmission of the excitatory process initiated by nerve impulses in ganglia and skeletal muscles are inclined to believe that it may be possible to demonstrate chemical mediators in the central nervous system essential for synaptic transmission. The evidence for the rôle of a chemical mediator in central transmission is as yet meager. The details should be sought in the reviews listed at the end of the chapter. Particularly noteworthy are the investigations of Nachmansohn on the esterasic power of various portions of the cerebrospinal axis. The pharmacological studies of Schweitzer and Wright on the effect of acetylcholine and anticholinesterase drugs on the functions of the central nervous system are likewise pertinent (pages 379–380). In addition, Mann, Tennenbaum and Quastel (1938) have shown that nervous tissue alone is capable of synthesizing acetylcholine *in vitro*. The observations of Haimovici and Cannon (page 344) that partly denervated spinal cord neurones become sensitized to acetylcholine and strychnine are highly suggestive, and Nachmansohn has demonstrated that strychnine is capable of inhibiting cholinesterase *in vitro* in concentrations which *in vivo* are capable of causing convulsions (page 258). Furthermore, Chute, Feldberg and Smyth (1940) observed that acetylcholine in significant amounts was released into the perfusion fluid flowing through the isolated cat's brain. Finally, it may be mentioned that Miller and coworkers (1940) demonstrated by use of the electrocorticogram that eserine

stimulated the motor cortex of cats and that acetylcholine produced similar stimulation but to a lesser degree. When acetylcholine was applied to the eserinized cortex, large stimulatory spikes were produced similar to those evocable by strychnine. The above are but a few of the suggestive lines of research which point to the possibility of chemical mediation of central synaptic transmission.

Chemical Classes of Nerves. The demonstration that acetylcholine acts as the chemical transmitter of impulses for nerves other than postganglionic parasympathetic nerves suggested to Dale the necessity of a new terminology which would classify nerves not anatomically but physiologically. He therefore proposed the terms "cholinergic" and "adrenergic" as functionally descriptive terms which designate the type of chemical activity by means of which nerve impulses transmit the excitatory process to effector organs.

Cholinergic Nerves. These include all nerves which release acetylcholine at their terminals. The category encompasses not only all postganglionic parasympathetic fibers, but also all autonomic preganglionic nerves, whether sympathetic or parasympathetic, the splanchnic (preganglionic) fibers to the adrenal medulla, the "sympathetic" fibers to sweat glands and certain blood vessels, and the somatic motor nerves to skeletal muscles.

Adrenergic Nerves. These include all nerves whose impulses act through the release of an epinephrine-like substance (adrenine; sympathin) and consist only of postganglionic sympathetic fibers. In Figure 31 are illustrated the main cholinergic and adrenergic nerve distributions in the body.

Nerve Regeneration. The experimental and clinical work on cross-suturing of nerves has demonstrated some interesting compatibilities and incompatibilities which, prior to the chemical mediation theory, were quite unexplainable. If one reviews this field in the light of chemical classes of nerves (Dale, 1935), it becomes apparent that cholinergic nerves can be cross-sutured to each other and establish functional union with effector end-organs or ganglia. Adrenergic nerves can be similarly interchanged with each other and establish functional contact with end-organs. Cholinergic fibers, however, cannot be united with adrenergic fibers and the two systems are mutually exclusive. This explains why even motor fibers to skeletal muscle can regenerate down the path of resected preganglionic autonomic nerves or postganglionic parasympathetic nerves and reestablish functional innervation of denervated structures. Also preganglionic autonomic nerves can make functional union with skeletal muscles when united to somatic motor nerves. The implications of these conclusions for the neurosurgeon are of the highest importance.

Autonomic Organization and Chemical Mediators. Under the discussion of anatomical organization of the autonomic nervous system, it was emphasized that the sympathetic nervous system is constructed for mass discharge as contrasted with the organization of parasympathetic nerves for discrete discharge. Also, under the discussion of the functions of the two systems, the rôle played by each in the economy of the organism was summarized. It is now possible to correlate this information with the existence of chemical mediators and chemical classes of nerves.

The sympathetic nervous system is anatomically organized so that one preganglionic fiber can make contact with a score or more of postganglionic fibers and thus greatly increase the area of distribution of nerve impulses. In addition, sympathetic nerve impulses are reinforced by epinephrine released from the adrenal medulla and by sympathin. The latter diffuses from structures receiving adrenergic innervation to circulate in the blood and affect distant organs. Both sympathin and epinephrine may exert their influence for many minutes and no drug analogous to eserine is necessary to protect them from destruction in the body. The parasympathetic nervous system is not only anatomically restricted to localized discharge, but the acetylcholine produced at cholinergic nerve endings is rapidly destroyed by the cholinesterase of the tissues and blood. Therefore it cannot circulate to distant parts. Furthermore, there is no special gland for the production of acetylcholine in the body as there is for epinephrine. It is these factors which allow the two divisions of the autonomic nervous system to function each in its characteristic manner in controlling the constancy of the internal environment of the body.

PHARMACOLOGICAL CONSIDERATIONS

The physiological advances outlined in the preceding pages have naturally had their parallel in the field of pharmacology, and it is desirable at this point to correlate these two phases of the subject. The concept of chemical mediation of nerve impulses, especially as applied to ganglia and skeletal muscles, has probably raised more problems in physiology than it has solved. This generally happens when new facts profoundly change old conceptions. It must be admitted that many aspects of the subject remain open for subsequent revision. The complexity of the problems involved makes it highly probable that our present ideas will require modification as investigations proceed. An acceptance of the hypothesis of chemical transmission, however, does not imply that one must discard all the older concepts concerning the nerve impulse. For the pharmacologist, at least, the theory of the intervention of chemical mediators at neuro-effector junctions, in whatever form they may be associated with the transmission of the excitatory process, allows a much clearer understanding of the actions of autonomic drugs, many of which were formerly classified purely as anomalies. When considered in the light of the chemical mediation theory, the complex and multiple actions of autonomic drugs lend themselves to an orderly, plausible and clinically fruitful interpretation.

Classification of Autonomic Drugs. Drugs acting on structures innervated by autonomic nerves either stimulate or depress the functions of effector cells. The older classification correlated these actions with the two anatomical divisions of the autonomic nervous system. Thus autonomic drugs were grouped as sympathetic stimulants and depressants, and parasympathetic stimulants and depressants. Such a division does not take into consideration the chemical classes of nerves, ganglionic sites of drug action, or somatic structures which respond to autonomic drugs.

With slight changes in the older classification, it is possible to group autonomic drugs in such a manner as to indicate their relation to each other and their sites of action. In order to do this, it is first necessary to have clearly in mind the fact that the drugs stimulate or depress effector cells and not nerve endings. A second point, which must be accepted provisionally and for which more evidence will be presented later, is that skeletal muscle cells respond to a number of autonomic drugs in the same manner as do autonomic ganglion cells, and that the cholinergic somatic motor nerves supplying such muscle cells are in some important respects quite analogous to cholinergic nerves supplying autonomic ganglia. With these facts in mind, autonomic drugs may be classified as in Table 18.

Site of Action of Autonomic Drugs. The older concept that the nerve terminals or endings were stimulated or depressed by drugs had to be abandoned when it was demonstrated that responses could be obtained even after complete denervation, or in embryonic structures before nerves had grown into the organ. The terms "myoneural junctions" and "receptive substances" were then used to indicate the hypothetical part of effector cells on which drugs were thought to act. In the opinion of some authorities (Loewi, 1936), it is highly doubtful whether these terms are any longer serviceable. It is claimed that autonomic drugs and chemical transmitters probably act directly on the effector cell, and that if the action of a drug is on some specific part of the cell, that part is probably not differentiated histologically but only physicochemically from the remainder. Other workers (Cannon and Rosenblueth, 1937) believe that inasmuch as the contractile substance is probably identical in all smooth muscle cells, there must be some differentiating substance in the muscle which is separate from the contractile material, and which determines whether contraction or relaxation occurs. For example, epinephrine relaxes the intestinal musculature, and acetylcholine contracts it. Furthermore, both acetylcholine and epinephrine cause contraction in some muscles, relaxation in others. It is therefore claimed that it is necessary to assume the existence of some differentiating substance which determines the particular responses, such as the H substance referred to under the discussion of the sympathins. Years ago, Langley found it necessary to hypothecate the presence of a "receptive substance" to explain these phenomena, and this expression is still employed.

TABLE 18

DRUGS ACTING ON CELLS INNERVATED BY:

	Nicotine	Pilocarpine Muscarine Arecoline	
Depressants ("Autonomic Blocking Agents")	Nicotine (mainly on ganglia) Curare (mainly on skeletal muscle) Acetylcholine (high concentrations) Physostigmine group ††	Atropine Scopolamine Hyoscyamine Homatropine	Ergotoxine Ergotamine Dioxane derivatives and sympatholytic agents

* Includes all preganglionic parasympathetic and sympathetic nerves, and all cerebrospinal somatic nerves to skeletal muscles (see text).

** Includes all postganglionic parasympathetic nerves, and certain sympathetic nerves to sweat glands and blood vessels.

† Includes all postganglionic sympathetic nerves except those to sweat glands and certain vascular beds.

†† These drugs act indirectly on cells by preventing cholinesterase from destroying acetylcholine.

(After Goodman, 1940)

Newer Concepts of Drug Actions. As Dale (1935) has pointed out, it is no longer correct to say that *acetylcholine* and *epinephrine* reproduce effects of parasympathetic and sympathetic nerves, but "it is truer to say that parasympathetic and sympathetic nerve impulses reproduce the peripheral effects of acetylcholine, because when they arrive at the nerve-endings, they liberate that substance in relation to the effector cells; and the same is true of the sympathetic nerve impulses . . ." Thus while it may be convenient descriptively to speak of pilocarpine, for example, as parasympathomimetic and ephedrine as sympathomimetic, it is not permissible so to label acetylcholine and epinephrine, which supply in themselves the chemicals liberated by autonomic nerves.

The autonomic drugs act on cells and not on nerve endings. Without describing the pharmacology of these drugs, it is necessary at this point to place their site of action more accurately in relation to the *sequence of events by which nerve impulses lead to responses in effector cells.* This sequence can be presented in the following scheme which, although incomplete, will serve present purposes:

1. Preganglionic nerve impulse.
2. Liberation of chemical mediator (acetylcholine) in ganglia.
3. Postganglionic nerve impulse.
4. Liberation of chemical mediator (acetylcholine or sympathin) at end-organ.
5. Combination of mediator with "receptive substance."
6. Specific response of muscle or gland.

Acetylcholine. The relation of this chemical to the mediation of nerve impulses has already been discussed. It functions at steps 2 and 4 in the above scheme; but when acetylcholine is injected into the body it acts directly on autonomic end-organs, ganglia and skeletal muscle. It was pointed out under the his-

tory of the chemical transmission theory that Dixon noted the fidelity with which the actions of the alkaloid muscarine simulated the effects of parasympathetic nerve stimulation. The similarity in action between acetylcholine and muscarine on autonomic effector organs (smooth muscles and glands) has given rise to the term "*muscarinic*" actions of acetylcholine to distinguish them from the effects on ganglia. For many years it was known that the alkaloid nicotine stimulated autonomic ganglia before paralyzing them. Acetylcholine also possesses the ability to stimulate ganglion cells in low concentrations and to depress them in high concentrations. Furthermore, both nicotine and acetylcholine have similar effects on skeletal muscles. For these reasons the stimulating actions of acetylcholine on ganglia and on voluntary muscles have been termed "*nicotinic*." The nicotinic and muscarinic actions of acetylcholine contrast not only in regard to the effector organs involved, but also in respect to the drugs which block these actions. Nicotine and curare block only nicotinic actions of acetylcholine, nicotine acting especially on ganglia and curare on striate muscle. Atropine prevents only the muscarinic actions. These points can be more readily appreciated by consulting the classification of drugs given in Table 18.

The nicotinic and muscarinic actions of acetylcholine can be strikingly demonstrated on the intestinal tract of a primitive fish known as the tench. This fish has an intestine composed of two muscular coats, the outer one being striated and the inner one smooth. Both types of muscle, however, are supplied by the vagus nerve, and therefore receive cholinergic innervation. The outer muscle coat responds to stimulation with a rapid contraction characteristic of skeletal muscle, and the inner layer responds with a slow contraction characteristic of smooth muscle (Frey, 1928). These facts are *schematically* presented in Figure 32. When the vagus is stimulated, the released acetylcholine excites both components of contraction and these are fused as diagramed in the figure. After *curare,* vagal stimulation yields only the smooth muscle or muscarinic component of contraction because the skeletal muscle is paralyzed. If *atropine* is applied and the vagus again stimulated, only the nicotinic or quick component of contraction is elicited, because atropine blocks the response of smooth muscle to acetylcholine. When *both curare and atropine* are given and the vagus is stimulated, no contraction occurs because both the nicotinic and muscarinic actions of acetylcholine are blocked.

Other *esters of choline,* such as *acetyl-betamethyl-choline* (mecholyl) and *carbaminoylcholine* (doryl) have been introduced into therapeutics in an attempt to obtain drugs which are not so readily susceptible to destruction by cholinesterase and therefore less evanescent in action, which have fewer nicotinic properties and more potent muscarinic effects, and which can be given orally. These drugs presumably act in a manner analogous to acetylcholine, but tend to show selective actions on particular effector cells.

Other Parasympathomimetic Alkaloids. The highly selective action of *pilocarpine* on structures innervated by postganglionic cholinergic nerves and its consequent simulation of the muscarinic and not the nicotinic effects of acetylcholine have never been satisfactorily explained. The same holds true for the alkaloids *muscarine* and *arecoline.* These three drugs are chemically distinct from acetylcholine, do not inhibit cholinesterase as does physostigmine, and act directly on effector cells. Muscular and glandular responses to these chemicals occur after complete nerve degeneration.

Physostigmine (*Eserine*) *and Prostigmine.* These drugs do not act on effector organs, and produce cell responses only by virtue of their ability temporarily to inhibit cholinesterase from destroying acetylcholine produced at cholinergic nerve endings. Thus they exert their effects indirectly in the same location as does acetylcholine, namely at steps 2 and 4.

Epinephrine and Sympathomimetic Drugs. The relation of epinephrine to the chemical mediation of adrenergic nerve impulses has already been discussed.

When epinephrine is injected into the body, it acts directly on smooth muscle and gland cells.

Sympathomimetic drugs such as *tyramine, ephedrine* and *benzedrine* are closely related chemically to epinephrine and presumably act directly on cells innervated by adrenergic nerves (page 424). They differ from the hormone mainly in that ergotoxine fails to reverse their excitatory actions and cocaine does not potentiate their effects.

Cocaine possesses certain sympathomimetic properties and is capable of potentiating adrenergic nerve stimulation and the action of epinephrine. The mechanism is not understood. It is not clear whether cocaine protects epinephrine and sympathin from oxidative destruction or whether it increases membrane permeability so that these substances may more readily diffuse into the reacting cells.

Atropine. Atropine has no effect on the nicotinic actions of acetylcholine but it specifically blocks all the muscarinic actions. Furthermore, it blocks muscarinic responses whether they are excitatory as in the intestine, or inhibitory as in the heart. Atropine prevents completely all the muscarinic responses to injected acetylcholine but is less effective in blocking certain effects of nerve stimulation. Although small doses of atropine prevent cardiac slowing or salivary secretion from occurring after nerve stimulation, large doses will not check the muscular responses of the intestine and the urinary bladder to nerve impulses. One can reasonably inquire why atropine fails to block the responses to certain nerve impulses if the latter act through the release of acetylcholine. The explanation lies in the fact that atropine probably causes a block between steps 4 and 5, that is, it prevents the mediator from penetrating the cell and reaching the receptive substance. When acetylcholine is released by cholinergic nerves, it is probably liberated inside the cell, and atropine evidently cannot prevent the intracellular action of acetylcholine. Histological evidence for this intracellular locus of release of acetylcholine is found in the fact that many autonomic nerve fibers end within the substance of the cell protoplasm. Unfortunately, our knowledge is not sufficiently complete to explain why atropine blocks the effects of certain cholinergic nerve impulses and not those of others. When atropine blocks the effects of nerve stimulation, it does not interfere in the least with the release of acetylcholine at cholinergic nerve endings. It only prevents acetylcholine from entering effector cells.

Ergotoxine and Ergotamine. Ergotoxine and ergotamine specifically block the effects of stimulation of adrenergic nerves. They prevent only excitatory responses to epinephrine or nerve stimulation, whereas atropine checks both excitatory and inhibitory responses. Furthermore, ergotoxine and ergotamine prevent all excitatory responses to adrenergic nerves in contrast to atropine which fails to block certain reactions to nerve stimulation. The ergot alkaloids do not prevent the release of the chemical mediator at adrenergic endings or the formation of sympathin E and I. They therefore do not interfere with the union of the mediator and the receptive substance. Consequently, ergotoxine and ergotamine must block autonomic responses by acting more distally than does atropine. Ergotoxine and ergotamine exert their effects between steps 5 and 6, that is, they block the contractile or secretory mechanism directly.

933F (Fourneau). This synthetic chemical, piperidinomethylbenzodioxan, is of considerable experimental interest because its sympatholytic action is analogous to the parasympatholytic property of atropine. It prevents injected epinephrine from producing responses but it does not effectively check the reactions to stimulation of adrenergic nerves. In this latter respect it differs from ergotoxine. The locus of action of 933F is the same as that for atropine, between steps 4 and 5.

This compound also blocks autonomic ganglia, thus acting between steps 2 and 3, a property not manifested by atropine or ergotoxine.

Curare and Nicotine. These two agents block the effects of the nerve impulse between steps 2 and 3. They block synaptic transmission through autonomic ganglia by acting directly on ganglion cells to render them unresponsive to injected acetylcholine or to acetylcholine released by preganglionic nerve impulses. That the ganglion cells are not paralyzed, however, is shown by the fact that they still respond when stimulated by potassium salts. Ganglionic paralysis by nicotine is preceded by a preliminary phase of stimulation, but this is not noted with curare.

Curare and nicotine also block the neuromuscular junctions in voluntary muscle. The pharmacological similarity between these junctions and autonomic ganglionic synapses will be pointed out. The action of curare and nicotine on skeletal muscle is such that the responses to both acetylcholine and nerve impulses are prevented. Nicotine and curare do not interfere with the release of acetylcholine when somatic motor nerves are stimulated. They therefore act by blocking skeletal muscle cells directly.

Autonomic Blocking Agents Do Not Interfere with the Release of Chemical Mediators. It is well to reemphasize that, although autonomic blocking agents interrupt the sequence of orderly events by which nerve impulses cause effector responses, in no instance do they prevent those impulses from releasing acetylcholine or sympathin. This fact has been repeatedly proved for all types of effector cells. Thus the locus of action of the autonomic blocking agents is always peripheral to the site of release of chemical mediators at nerve endings.

Drugs Having Minor Autonomic Actions. A number of chemical agents have partial or indirect autonomic actions. These include yohimbine, apocodeine, guanidine, strychnine, xanthines and the barbiturates. In the last analysis, the effector cells have distinct chemical properties, and it is not surprising that among the vast number of organic chemicals there exist a few substances which can more or less specifically stimulate or depress certain autonomic cell functions.

Potassium Ions. The ions of potassium occupy a peculiar pharmacological rôle due to their ability to stimulate structures innervated by cholinergic nerves. The neuromimetism of potassium ions is not yet fully understood, nor is it known what part these ions normally play in the physiology of the visceral nervous system. It does not appear, however, that potassium occupies a significant place in the mechanism of action of autonomic drugs. The actions of potassium ions in this respect are more fully discussed on page 596.

Skeletal Muscle Neuropharmacology. The possible rôle of acetylcholine in the mediation of somatic nerve impulses to skeletal muscle has clarified several puzzling phenomena for which pharmacologists previously had no adequate explanation. Although physostigmine and pilocarpine have many actions in common, the former drug causes definite skeletal muscle twitchings not produced by the latter. Nicotine, which is viewed as a drug primarily acting to paralyze autonomic ganglia, is also capable of paralyzing voluntary muscle. Why these drugs act on skeletal muscle when the bulk of anatomical evidence shows that the latter receives no autonomic innervation remains a dilemna which can best be resolved by the theory that somatic motor nerves function through the acetylcholine mechanism. Physostigmine thus affects skeletal muscle by preserving the locally produced acetylcholine from destruction by cholinesterase. The failure of physostigmine to act on skeletal muscle after its nerves are cut and degenerated adds support to this theory, because the drug acts only to preserve acetylcholine and when the latter is not present (as after nerve degeneration) physostigmine has no effect.

Acetylcholine causes both striped and smooth muscles to contract. This is true despite the definite anatomical and physiological differences between these muscles. Although a sharp distinction exists between smooth and skeletal muscle, many similarities can be noted between the skeletal muscle and the postganglionic nerve fiber. Elliot suggested many years ago that the conducted disturbance in skeletal muscle is the physiological equivalent of the postganglionic nerve impulse. There are reasons today to believe this suggestion may be true (Rosenblueth, 1936). If it is correct, then the neuromuscular junctions (motor-end plates) become analogous to the synapses in autonomic ganglia. The cholinergic nerve to a skeletal muscle fiber and that to a ganglion cell are both medullated, and both come directly from cells lying inside the central nervous system. Again, a single spinal motor nerve fiber may supply 100 or more skeletal muscle cells, and the preganglionic autonomic nerve fiber may synapse with a score or more of ganglion cells. Furthermore, the reactions of ganglion cells and skeletal muscle cells to drugs are quite similar, as is indicated in the classification of drugs in Table 18. Both structures are stimulated by acetylcholine and physostigmine, unaffected by pilocarpine and atropine, and functionally severed from the central nervous system by nicotine and curare.

As far as it is now understood, the pharmacology of the autonomic synapse is similar in all major respects to that of the junction between the spinal motor nerve and skeletal muscle. Both structures are relay sites between two waves of impulse conduction, and acetylcholine is apparently a major factor in the transmission of the excitatory state.

Clinical Applications. The concept of transmission of nerve impulses to skeletal muscle by acetylcholine has opened a new field of therapy for certain myopathic disorders. In the case of myasthenia gravis, at least, the mechanism of action of drugs effective against the profound muscular weakness characterizing this disease can be correlated with the chemical mediation of somatic motor nerve impulses. The pathological physiology of myasthenia gravis may be due to: (1) a deficiency in the amount of acetylcholine produced at motor nerve endings, (2) an increase in muscle cholinesterase, or (3) the existence of some abnormal substance or metabolite with a curare-like action which elevates the threshold of skeletal muscle to the effects of nerve impulses. Which of these factors is involved is not known. Nevertheless, physostigmine, prostigmine and certain choline esters give striking relief and return muscular strength to normal. Regardless of the exact etiology of the disorder, the action of these drugs tends to increase the effective concentration of acetylcholine at neuromuscular junctions.

Myotonia congenita is in pharmacological contrast to myasthenia gravis. Theoretically, at least, the symptoms of this syndrome could be explained on the basis of an excess of acetylcholine, and this in turn could be due to the reverse of any of the three factors listed in the preceding paragraph, although it is more likely that the muscle fibers are abnormally sensitive to acetylcholine. Drugs effective in myasthenia gravis aggravate the symptoms of myotonia congenita. In *familial periodic paralysis,* choline esters and potassium salts have given relief.

These examples are given not to present fully solved problems but rather to indicate the many therapeutic ramifications of this field and to show that clinical fruit is ripening on what may have appeared to be a purely academic tree.

Sensitization to Drugs by Nerve Degeneration. For many years it has been known that certain effector structures become more sensitive to drugs when deprived of their nerve supply. Several interesting facts, some of them with direct clinical applicability, have evolved from a reexamination of sensitization in relation to the chemical mediation theory. When postganglionic nerves are cut and degenerate, effector organs become more responsive to chemical mediators. An example of this is seen in the "paradoxical pupillary reaction" (Langendorf, 1900). This reaction consists in the wide dilatation of the sympathetically denervated pupil under certain conditions of sympatho-adrenal discharge. It was first described by Budge (1855) but it was not fully appreciated until many years later (Elliot, 1905, 1912) that sympathetically denervated structures are excessively stimulated by epinephrine.

The phenomenon of sensitization is clearly seen in the smooth muscle of blood vessels in animals and man (*see* Freeman, Smithwick and White, 1934; Ascroft, 1937), and it has significance for the type of neurectomy performed for peripheral vascular disturbances. The following oft-quoted case provides an instructive example. A surgeon performed a cervicodorsal sympathetic ganglionectomy on a woman for Raynaud's disease and the immediate results were apparently quite good. Several days later, he demonstrated the patient to a group of medical students and noted to his surprise that when he pulled back the bedclothes the hands were cold and blanched. A few hours later he revisited the patient alone and the hands were warm and pink. The explanation is that the blood vessels in the denervated area were sensitized to epinephrine and sympathin released by the excitement occasioned by the visit of the medical students. This resulted in marked vasoconstriction in the upper extremities. No such sympatho-adrenal discharge occurred when the doctor visited the patient alone.

It is now clear why for many years better results were obtained by sympathectomies performed for the legs than was the case for the arms. The classical operation for the upper extremity was in reality a postganglionic sympathectomy. In the lower extremity, the lumbar sympathectomy which was performed left intact the postganglionic fibers and thus it was really a preganglionic resection. The latter does not cause degeneration of the nerves to vessels which are therefore not sensitized. It does, however, interrupt the connection of the peripheral effector organs with the central nervous system and cuts off noxious nerve impulses. The Smithwick (1936) preganglionic sympathectomy for the upper extremity is said to yield better results in peripheral vascular diseases than does sympathetic ganglionectomy (postganglionic resection). Not all neurosurgeons, however, agree with this point of view (*see* Fatherree, Adson and Allen, 1940).

Not only does section of excitatory adrenergic nerves result in sensitization of the denervated smooth muscles but resection of inhibitory adrenergic nerves also causes increased sensitivity of the denervated effector organs. Thus, Luco (1937) demonstrated an increased responsiveness of the denervated rabbit intestine and non-pregnant cat uterus to epinephrine, both structures being relaxed by the drug. Similarly, Youmans (1938) showed that the sympathetically denervated dog's intestine was three times more sensitive to the inhibitory effect of epinephrine than was the normal bowel.

Structures innervated by cholinergic nerves are also sensitized to chemicals by interruption of their nerve supply. For example, after excision of the ciliary ganglion, Shen and Cannon (1936) noted an enhanced response of the paralyzed sphincter muscle of the iris to acetylcholine.

Gland cells as well as smooth muscle cells show increased responsiveness to the chemical mediators when their autonomic innervation is interrupted. This has been demonstrated in the lacrimal and submaxillary glands (Maes, 1938; Simeone and Maes, 1939).

Autonomic ganglion cells manifest an increased sensitiveness to acetylcholine and certain other chemicals when they are deprived by section of their preganglionic innervation. Thus, when the preganglionic fibers to an autonomic ganglion are cut, the ganglion cells remain intact but quickly become abnormally sensitive to acetylcholine. It can be shown experimentally, for example, that preganglionic nerve section causes a four-fold increase in the responsiveness of ganglion cells (superior cervical) to acetylcholine (Rosenblueth and Cannon, 1939). Acetylcholine, however, normally does not escape into the circulation from its sites of release due to effective hydrolysis by cholinesterase. Fortunately, for this reason ganglionic sensitization in patients subjected to preganglionic neurectomy is not likely to have adverse clinical reverberations.

Not only are smooth muscles, gland cells and ganglion cells sensitized by nerve degeneration, but skeletal muscles are also sensitized to acetylcholine by degeneration of their motor nerves. In 1863, Philipeaux and Vulpian noted that when the hypoglossal nerve to a dog's tongue was cut, the tongue muscles could be made to contract slowly by stimulation of the sensory lingual nerve. Rogowicz (1885) noted a similar phenomenon in the facial muscles, and Sherrington (1894) in the muscles of the hind leg. Many erroneous explanations were advanced from time to time but it is now known that these slow contractures are caused by acetylcholine leaking onto the denervated sensitized skeletal muscles. The acetylcholine is probably produced locally by the cholinergic vasodilator fibers supplying the blood vessels of the skeletal muscles and these nerve fibers are not interrupted by cutting the spinal motor nerves. The degree of increased sensitivity to acetylcholine of denervated skeletal muscles in mammals has been estimated to be as great as a thousand-fold (Brown, Dale and Feldberg, 1936).

Finally, it has been demonstrated that nerve cells of the central nervous system become sensitized when they are "denervated," *i.e,* deprived wholly or in part of their normal nerve connections. Thus, Haimovici and Cannon (*see* Cannon, 1939), employing the technic of semisecting the lower portion of the spinal cord in animals and testing the responses of the two quadriceps muscles, found that acetylcholine stimulated the denervated cells of the spinal cord in doses which did not affect the intact cells, as judged by the muscular responses obtained. Likewise, the action of strychnine on the spinal cord caused many more muscle contractions on the cut than on the control side, a fact of interest in view of the possible anticholinesterase property of this drug (page 258). The demonstration that spinal neurones respond to partial denervation by an increased sensitiveness to chemicals is in keeping with the theory that chemical mediators may be concerned with central synaptic transmission.

Mechanism of Sensitization by Denervation. The mechanism of sensitization of denervated structures is not understood. Nor is it clear why maximal sensitization requires 14 to 16 days to develop in smooth muscles supplied by adrenergic nerves (Hampel, 1935) but only a few to 24 hours in the case of smooth muscles receiving cholinergic nerves. Muscles become endowed with a specific responsiveness to chemical mediators as a result of the establishment of nerve connections. Armstrong (1935) showed that the growth of vagal fibers into the embryonic myocardium of the fundulus causes the heart to become very sensitive to acetylcholine. After nerve degeneration, this sensitivity of effector organs to chemical mediators and certain drugs evidently becomes greatly enhanced. The extent of this increased responsiveness can be appreciated from the fact that the totally denervated heart responds with acceleration of rate to one part of epinephrine in 1,400,000,000. Regeneration of the nerve supply of a denervated organ results in a gradual loss of the abnormal sensitiveness (Simeone, 1937).

Several possibilities exist to explain the sensitization of effector cells evoked by denervation, including decreased ability to destroy the chemical mediator, altered physical properties in contractile cells, increased amount of stored precursor of the chemical mediator, and enhanced permeability of effector cells. The most plausible explanation is that the permeability of the membrane of the effector cell is increased when the nerve supply degenerates. Two lines of evidence exist for this interpretation. In the first place, the increased sensitivity is not absolutely specific for acetylcholine and epinephrine, but also exists to a certain extent for other stimulating agents. For example, the denervated nictitating membrane is sensitized not only to epinephrine but also to acetylcholine, pilocarpine, histamine and potassium ions. Denervated skeletal muscle is unusually responsive to nicotine and potassium as well as to acetylcholine (Dale and Gasser, 1926). The same is true of autonomic ganglia. The second point is that denervation in smooth muscle results in a lessened electrical potential accompanying the contraction. This may be the result of a diminished polarization of the cell membrane due to an increase in cell permeability.

Law of Denervation. The observations recorded in the foregoing paragraphs have prompted Cannon to suggest that there exists a law of denervation, which may be stated as follows (Cannon, 1939): "When in a series of efferent neurones a unit is destroyed, an increased irritability to chemical agents develops in the isolated structure or structures, the effect being maximal in the part directly denervated." The pertinent literature and physiological significance of the phenomena of sensitization following denervation have been reviewed by Cannon (1939).

CHAPTER 20

DRUGS STIMULATING STRUCTURES INNERVATED BY CHOLINERGIC NERVES (PARASYMPATHOMIMETIC DRUGS)

I. CHOLINE ESTERS: ACETYLCHOLINE, ACETYL-BETA-METHYLCHOLINE AND CARBAMINOYLCHOLINE

Autonomic drugs stimulating structures innervated by cholinergic nerves may conveniently be divided into three groups, as follows: (1) the choline esters—*acetylcholine, acetyl-β-methylcholine* and *carbaminoylcholine;* (2) the inhibitors of cholinesterase—*physostigmine* (*eserine*) and *prostigmine;* and (3) the older alkaloids, *pilocarpine, arecoline* and *muscarine*. Collectively, all these drugs are known as parasympathomimetic agents, but the three groups contrast sharply in many respects. Their relation to each other and the effector organs upon which they act are indicated in Table 18.

ACETYLCHOLINE

Acetylcholine is a substance of great interest to physiologists and pharmacologists because it produces responses in effector cells which simulate those obtained from stimulation of cholinergic nerves. Its clinical uses, however, are limited because of its instability and consequent transient effects in the body. Nevertheless, a knowledge of the actions of acetylcholine enables one better to understand the other more useful parasympathomimetic agents.

Historical. Acetylcholine was first synthesized by Baeyer in 1867, but for many years it had only a chemical interest. At the turn of the century, Hunt (1899) noted that adrenal extracts from which epinephrine had been removed caused a fall in blood pressure, and although he identified the presence of choline in the extract, he suggested that some precursor of choline, perhaps an ester, was the vaso-depressor agent. In 1906, Hunt and Taveau showed that acetylcholine was 100,000 times more active than choline in causing a fall in blood pressure. Later (1910, 1911), these same investigators reported on the properties of other choline esters including acetyl-β-methylcholine. Ewins (1914) then identified acetylcholine in certain extracts of ergot and Dale (1914), stimulated by this discovery, examined the pharmacological properties of acetylcholine in considerable detail. Dale noted that the chemical mimicked the effects of stimulation of parasympathetic nerves and introduced the term "parasympathomimetic" to describe its properties. He observed that acetylcholine had an evanescent action and that atropine annulled completely the so-called parasympathetic effects. After atropine, however, acetylcholine manifested new properties, namely, an ability to stimulate all autonomic ganglion cells in a manner similar to nicotine. The distinction between peripheral effects on glands and smooth muscle cells (*muscarinic action*) and those on ganglion cells and skeletal muscles (*nicotinic action*) soon occupied the attention of workers in this field and other esters of choline as well as phosphonium, arsonium, stibonium and sulfonium bases were investigated for their pharmacological properties (Hunt and Renshaw, 1925, *et seq.;* Simonart, 1932; Comroe and Starr, 1933; Molitor, 1936; and others).

Parallel with the foregoing studies came the important discovery of Loewi concerning the rôle of acetylcholine in the chemical mediation of the nerve impulse and the subsequent elaboration of the hypothesis of this substance as the transmitter of the excitatory state across ganglionic synapses and neuromuscular junctions in voluntary muscles. The story of these discoveries and their profound importance for physiology and pharmacology has been presented in detail (Chapter 19).

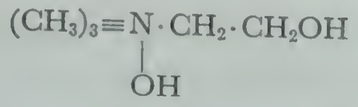
Relationship Between Chemical Structure of Choline Derivatives and Pharmacological Actions. Choline, in common with other quaternary ammonium bases, possesses three distinct types of pharmacological action: muscarinic, nicotinic and curariform. The manifestations and significance of these types of responses and the drugs which antagonize them have been discussed (Chapter 19). Numerous esters, ethers and other derivatives of choline have been studied in an attempt to find the basis for the susceptibility of the compounds to hydrolytic destruction in the body by cholinesterase, the relative prominence of the three types of actions, and the special affinities of the drugs for particular autonomic effector organs. Only certain salient features can be presented; the details may be found in pertinent publications (Hunt and Taveau, 1911; Hunt and Renshaw, 1925, *et seq.;* Simonart, 1931, *et seq.;* von Oettingen and Elveleth, 1932; Molitor, 1936; and others).

Derivatives of choline may exert all, none or varying combinations and intensities of the three basic actions listed. For example, replacing the alcoholic hydroxyl by a carboxyl group (to yield betaine) results in a compound which is practically inert. Methyl and ethyl esters of β-methylcholine cause only muscarinic responses. The ethers of triethylammonium compounds, on the other hand, manifest only curariform effects. Lengthening of the side-chain of choline usually increases its muscarinic potency, whereas shortening the chain increases the nicotinic action. Esterification of the alcoholic hydroxyl of choline also increases the muscarinic action. Esters of choline are rapidly hydrolyzed by the blood and tissues whereas ethers of choline are unaffected by cholinesterase. Also, the esters are far more effective in liberating epinephrine from the adrenal medulla than are the ethers (Simonart, 1932).

In regard to the clinically useful compounds, acetylcholine resembles choline itself except that it is from 500 to 100,000 times more potent, dependent on the particular response which is being observed. Acetyl-β-methylcholine resembles acetylcholine except that it lacks the marked stimulating action on autonomic ganglia. Carbaminoylcholine, on the other hand, has a greater nicotinic effect than acetylcholine. The ethyl ether of β-methylcholine resembles acetyl-β-methylcholine except that it is much more stable. In addition, this compound serves to illustrate the occasional affinity of these drugs for specific effector organs. The ether derivative causes marked miosis upon systemic administration to cats whereas this response is not seen either after esters of β-methylcholine or lethal doses of the ethyl ether of choline (Simonart, 1932). Optical activity also influences the pharmacological behavior of the choline derivatives. For example, the levorotatory acetyl-β-methylcholine exerts a much smaller muscarinic effect than the dextrorotatory isomer, but only the latter is hydrolyzed by the cholinesterase of cat or rabbit serum. Yet neither isomer exerts any action on autonomic ganglia and both are active on denervated skeletal muscle (Simonart, 1938). Certain salient features of the choline compounds employed in therapeutics are shown in Table 19.

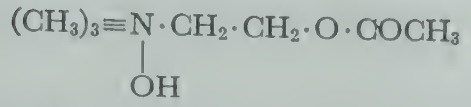
Chemistry, Preparations, Doses and Administration. The structural formula of acetylcholine and its relationship to choline and to other choline esters are as follows:

Choline



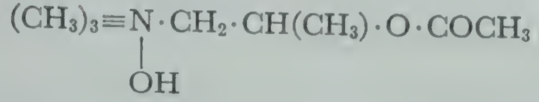
$(CH_3)_3{\equiv}\underset{\displaystyle OH}{\underset{|}{N}}{\cdot}CH_2{\cdot}CH_2OH$

Acetylcholine



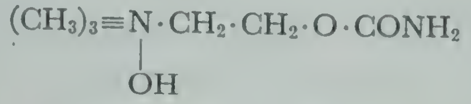
$(CH_3)_3{\equiv}\underset{\displaystyle OH}{\underset{|}{N}}{\cdot}CH_2{\cdot}CH_2{\cdot}O{\cdot}COCH_3$

Acetyl-β-methylcholine



$(CH_3)_3{\equiv}\underset{\displaystyle OH}{\underset{|}{N}}{\cdot}CH_2{\cdot}CH(CH_3){\cdot}O{\cdot}COCH_3$

Carbaminoylcholine



$(CH_3)_3{\equiv}\underset{\displaystyle OH}{\underset{|}{N}}{\cdot}CH_2{\cdot}CH_2{\cdot}O{\cdot}CONH_2$

Acetylcholine is also closely allied to muscarine. The drug is not official and is not described in N.N.R. It is available, however, in the form of the chloride and bromide salts. *Acetylcholine Chloride* and *Acetylcholine Bromide* are white, odorless, hygroscopic, crystalline powders. Both salts are very soluble in water and alcohol and are easily decomposed by heat and alkali. They should be kept tightly stoppered. Sterile ampules containing measured amounts of the dry salts are available for preparing aqueous solutions for parenteral injection.

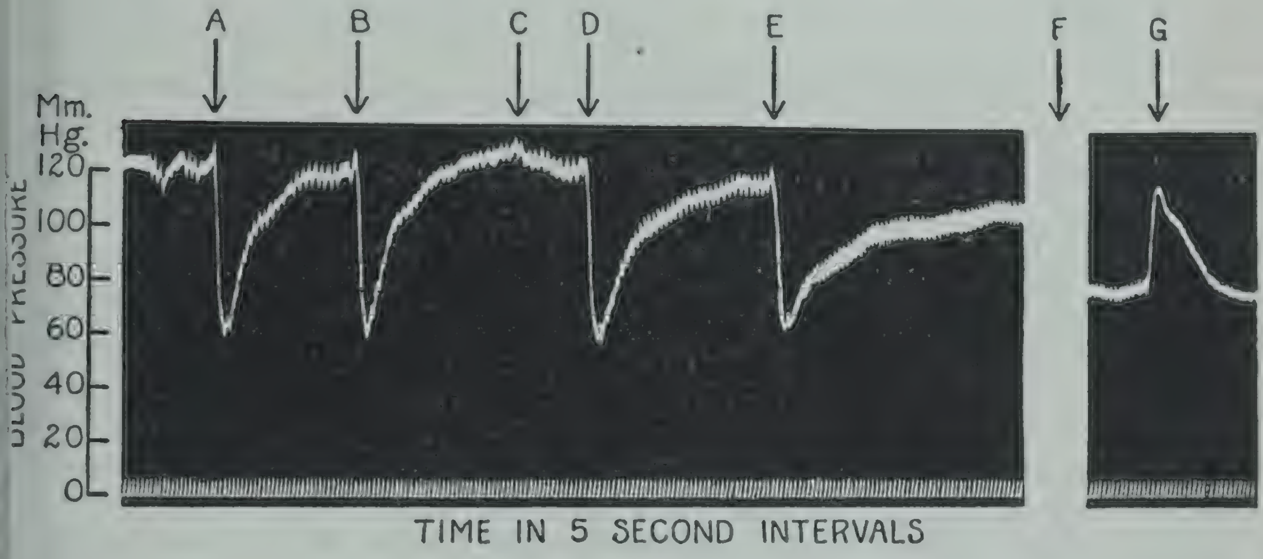


FIGURE 33. *General autonomic pharmacology: the effect of serum cholinesterase on acetylcho- ne and carbaminoylcholine, and the demonstration of the stimulant (nicotinic) action of cetylcholine on autonomic ganglia.*

A. Intravenous injection of 10 micrograms of acetylcholine in a cat under pentobarbital nesthesia causes a typical vasodepressor response. *B.* Injection of 10 micrograms of acetylcholine, cubated for one one hour with dog serum plus a minute amount of eserine, manifests the aracteristic vasodepressor action. The eserine prevented the dog serum cholinesterase from estroying the acetylcholine. *C.* Injection of 10 micrograms of acetylcholine, similarly incubated r one hour with dog serum but without the addition of eserine, fails to elicit a fall in blood ressure due to destruction of the drug by cholinesterase. *D.* Injection of 10 micrograms of carminoylcholine causes an equal fall in blood pressure. Observe the longer duration of action e to slower destruction of this compound in the body. *E.* Injection of 10 micrograms of carminoylcholine, incubated for one hour with the same amount of dog serum as in *C* above, ntinues to elicit a fall in blood pressure without a decrement, indicating that this choline rivative is quite stable and resistant to hydrolytic destruction by cholinesterase. *F.* Interval of minutes during which the test cat was atropinized and eserinized. *G.* Injection of 500 microms of acetylcholine: note the rise in blood pressure resembling that produced by a small dose of inephrine and caused by the nicotinic effect of acetylcholine, that is, a sympatho-adrenal disarge. Atropine prevents the vasodepressor muscarinic response, and eserine protects the etylcholine from destruction in the body. For further details, see text.

The *dose* depends upon the results desired. The drug is practically inert when taken by mouth due to its hydrolytic destruction by gastro-intestinal enzymes and consequently it must be given intramuscularly, subcutaneously or by iontophoresis. The dose by injection varies from 40 to 200 mgm.

Mechanism of Action. Acetylcholine apparently acts directly upon effector cells to elicit their characteristic responses. Whether this action concerns the receptive substance or the reactive material of the cell is unknown. The mechanism of action of acetylcholine is more fully elaborated elsewhere (page 338). Cells reacting to the drug fall into two distinct categories, those cells innervated by (1) postganglionic cholinergic nerves (*i.e.,* smooth muscle and gland cells) and (2) preganglionic nerves and somatic motor nerves (*i.e.,* autonomic ganglion cells and skeletal muscle fibers). The actions of the drug on these two groups of effector cells have been termed the *muscarinic* and *nicotinic* actions, respectively. The details and significance of these two types of response are given on page 339. Atropine blocks only muscarinic actions of acetylcholine; nicotine (in large doses) and curare, only nicotinic actions (pages 340, 341) (Table 18).

The responses to acetylcholine in the body are further characterized by their transient and evanescent nature (Figure 33). This is due mainly to the fact that acetylcholine is hydrolyzed to acetic acid and the pharmacologically impotent choline by *cholinesterase,* an enzyme present in blood and tissues. The properties, distribution and physiological importance of this enzyme are fully presented in the introductory chapter to the autonomic drugs. Eserine and prostigmine prolong and intensify the responses to injected acetylcholine by inhibiting cholinesterase.

Pharmacological Properties

By reference to the responses of effector organs to cholinergic nerve impulses, as listed in Table 17, one can predict accurately the effects of the administration of acetylcholine. Certain responses, however, are not detectable unless special technics are used to elicit them. Thus, the rise in blood pressure due to the nicotinic action of acetylcholine on the sympathetic ganglion cells and on the adrenal medulla does not become manifest unless the fall in blood pressure, due to the muscarinic action of the drug on smooth muscle cells of blood vessels, is prevented by atropinization. This is due to the fact that the muscarinic responses to acetylcholine normally predominate. In this connection, it may be stated that the evanescent character of the responses to acetylcholine is due not only to the hydrolytic destruction of the ester by cholinesterase, but also to the fact that the nicotinic actions of the drug are in opposition to the muscarinic. The acetylcholine-induced sympatho-adrenal discharge tends to counteract many of the peripheral autonomic effects of the drug, as is evident from an inspection of Table 17. The major characteristics of acetylcholine in comparison with allied choline derivatives are shown in Table 19.

Cardiovascular Action. Typical cardiovascular responses to acetylcholine can only be seen when a sufficiently large dose is given to an experimental animal. The drug then causes vasodilatation, especially of smaller blood vessels, a fall in blood pressure, various grades of heart block from partial to complete auriculoventricular dissociation, and cardiac slowing which may proceed to complete asystole.

Various arrhythmias and electrocardiographic abnormalities can be produced in experimental animals by intravenous injection of acetylcholine (Goldenberg and Rothberger, 1934; Noth, Essex and Barnes, 1939). These include a decrease in the height, notching and diphasic character of the P wave, partial and complete heart block, ventricular standstill of varying duration, and auricular fibrillation and auricular tachycardia. The drug appears to cause only slight depression of the sino-auricular node and more marked depression of the auricular musculature, the auriculoventricular node and the bundle of His. These actions are favorable for abolishing paroxysmal tachycardia of auricular or A-V nodal origin. Starr (1936) has reported the interesting fact that quinidine diminishes or abolishes the ability of acetylcholine to slow the cardiac rate in intact anesthetized animals or in isolated hearts. This action of the alkaloid is not identical with that which blocks the response of the heart to vagal stimulation. Patients with paroxysmal tachycardia may thus not respond to therapy with choline esters if they are receiving quinidine.

TABLE 19

COMPARATIVE CHEMICAL, PHYSIOLOGICAL AND PHARMACOLOGICAL PROPERTIES OF ACETYLCHOLINE, ACETYL-BETA-METHYLCHOLINE AND CARBAMINOYLCHOLINE

Drug	Chemical Properties		Physiological Properties		L.D.$_{50}$ in Rats in Mgm/Kg			Equally Effective Doses on Rabbit's Blood Pressure in Mgm/Kg			Minimum Effective Cathartic Dose in Dogs in Mgm/Kg	
	Stability in Air	Stability in Water	Susceptibility to Cholinesterase	Nicotinic Action	Intravenous	Subcutaneous	Oral	Intravenous	Subcutaneous	Oral	Subcutaneous	Oral
Acetylcholine	Hygroscopic	Unstable	++	+	22	250	2500	0.002	1.0	1000	0.8	40
Acetyl-β-methylcholine	Hygroscopic	Unstable	+	−	20	75	750	0.002	0.2	50	0.05	25
Carbaminoylcholine	Non-hygroscopic	Stable	−−	++	0.1	4	40	0.002	0.1	2	0.01	0.25

Molitor, 1936.

The effects of acetylcholine on the coronary arteries has been studied by several investigators and the results vary considerably depending on the technic, doses of drug and species employed (Smith and associates, 1926; Wedd and Fenn, 1933; Orzechowski, 1933; Goldenberg and Rothberger, 1934). In cat, dog and rabbit hearts, Wedd (1936) found that acetylcholine caused a prompt increase in coronary outflow which was followed by a decrease. The vasodilator effect was thought to be caused by the muscarinic component of action of the drug; the vasoconstrictor effect, by the nicotinic. Katz and associates (1938) observed that only coronary vasodilatation occurred from acetylcholine in the perfused isolated dog heart, whereas both coronary dilatation and constriction were produced by the drug in isolated cat hearts. All effects of acetylcholine on the coronary arteries of both species were abolished by atropine. The finding that acetylcholine causes only coronary vasodilatation in the dog heart, an organ similar at least experimentally to the human heart, seriously challenges the currently accepted view that cholinergic (vagal) impulses to the coronary arteries produce vasoconstriction, and supports the experimental results of Katz and Jochim (1939) who found in dogs that the only vasoconstrictor fibers to the coronaries are adrenergic in character and run in the sympathetic pathway, and that the vagal fibers are cholinergic vasodilators. No cholinergic vasoconstrictor fibers were found in the vagi (page 405) (Katz and Lindner, 1939).

In man, the use of therapeutic doses of acetylcholine produces little change other than vasodilatation and slight fall in blood pressure. This is due to the rapid destruction of the compound and to the efficient compensatory cardiovascular reflexes mediated through the vasosensitive carotico-aortic receptors. In addition, the sympatho-adrenal discharge produced by the nicotinic action of acetylcholine tends to counteract any marked alterations in the heart and blood vessels. Only when large doses are administered intravenously can responses be elicited similar to those obtainable in anesthetized animals. Ellis and Weiss (1932) studied the cardiovascular responses of healthy men to the intravenous and intra-arterial injection of acetylcholine. They found that continuous intravascular injection of solutions of acetylcholine could be made for prolonged periods of time without symptoms or objective signs and with no evidence of cumulative action. Twenty to 60 mgm per minute had to be infused in order to obtain minimal effects. The maximum tolerated dose producing toxic symptoms was 90 to 140 mgm per minute. As much as one gram was injected over a period of 10 minutes. Thus man can destroy the drug rapidly and can therefore tolerate extremely large amounts. This is in sharp contrast to his sensitivity to acetyl-β-methylcholine, which Weiss and Ellis (1934) have shown can be tolerated intravenously only in doses 1/200 that of acetylcholine (Figure 34).

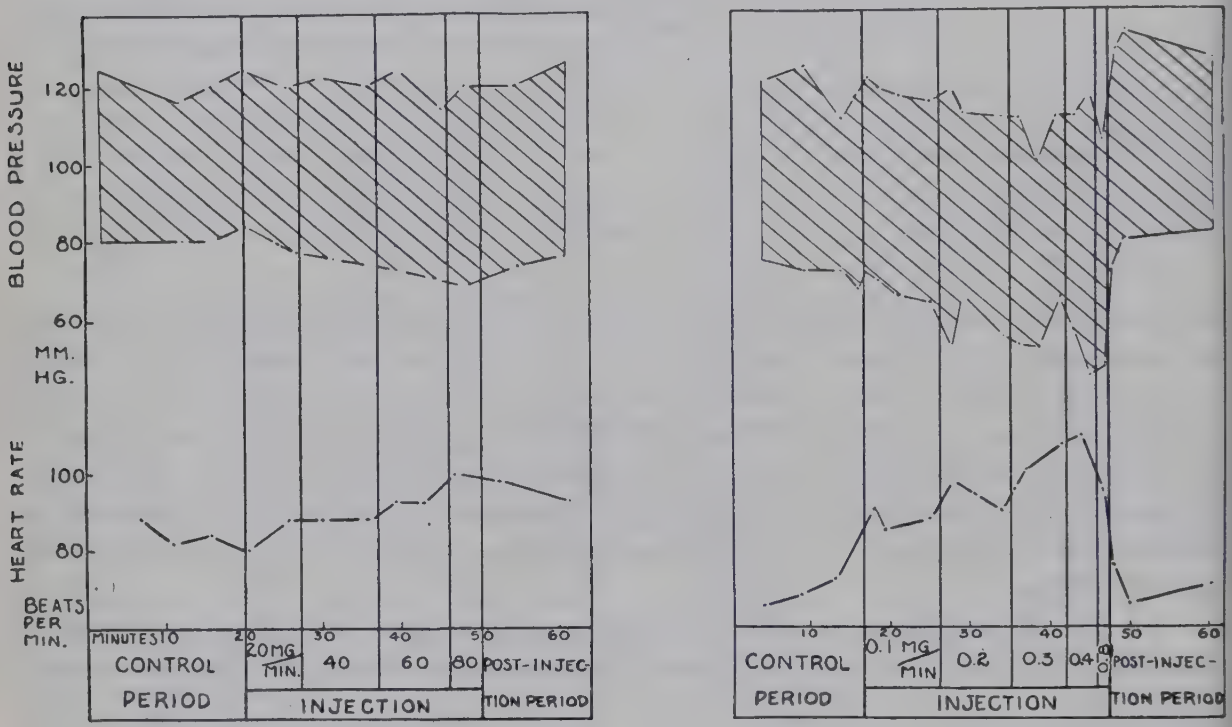

FIGURE 34. *The comparative effect of increasing rates of intravenous infusion of acetylcholine and acetyl-β-methylcholine on the arterial blood pressure and on the heart rate in a normal adult.*

Because acetyl-β-methylcholine is less rapidly inactivated in the body by cholinesterase, it is approximately 200 times more potent than acetylcholine in evoking cardiovascular responses in man. Whereas the intravenous infusion of acetylcholine at the rate of 20 mgm per minute produces minimal effects and 80 mgm produces marked effects, it requires only 0.1 mgm of acetyl-β-methylcholine per minute to evoke minimal and 0.4 mgm marked responses. Both compounds can be infused at a rate producing definite symptoms for prolonged periods without evidence of cumulative action. For a description of the symptoms and signs observed, see text. (After Weiss and Ellis, 1934. Courtesy of the *Journal of Pharmacology and Experimental Therapeutics.*)

Symptoms and signs observed during acetylcholine administration were directly proportional in intensity to the size of the dose and included flushing of the skin, warmth, increase in skin temperature, throbbing in the head, palpitation, relaxed peripheral arteries and bounding pulse, profuse sweating, salivation and lacrimation, substernal constriction accompanied by inspiratory difficulty and slight cough, and nausea and vomiting when the dose was pushed to the limit of tolerance. Symptoms remained at a given level of intensity as long as the dose was unchanged, and all of them subsided without residual effects within a few minutes after cessation of the injection. Bradycardia was never noted. Indeed, cardiac rate was moderately speeded, obviously a compensatory effect. Systolic and diastolic blood pressures were never lowered significantly by the acetylcholine infusion, and changes in cardiac output were not noted. In a later study, Weiss and Ellis (1934) also demonstrated that acetylcholine caused no increase in circulatory velocity. The injection of acetylcholine into the femoral artery caused regional dilatation of arteries and arterioles as shown by bright flushing, marked sweating, increased skin temperature, and enhanced pulse pressure in the vessels as measured by their oscillometric excursion. A marked local increase in total blood flow was indicated by a fall in the arteriovenous-oxygen difference of the blood in the femoral artery and vein. Systemic effects did not occur from intra-arterial injection of the drug.

Large doses of acetylcholine given orally to patients produce no pharmacological actions. Kovacs and coworkers (1936), however, found that an occasional patient showed typical reactions from the oral ingestion of two grams of the drug. When large doses of acetylcholine (50 to 100 mgm) were injected subcutaneously in human beings, both Starr and coworkers (1933) and Weiss and Ellis (1934) noted practically no systemic effects, and Carmichael and Fraser (1933) injected doses of as much as 500 mgm intramuscularly or subcutaneously without producing alterations in pulse rate or blood pressure. Carmichael and Fraser observed transient bradycardia and fall in blood pressure when 10 to 30 mgm were injected very rapidly intravenously. In other respects, their observations corroborate those of Ellis and Weiss.

Gastro-Intestinal Actions. Although sufficiently large doses of acetylcholine cause increased tone, amplitude of contraction and peristalsis in the stomach and intestine and stimulate gastro-intestinal secretions, practically no effect is noted in man even when doses approaching the limit of tolerance are injected intravenously. Nausea and vomiting were the only symptoms referable to the alimentary canal observed in the experiments of Ellis and Weiss cited. The transient effects of acetylcholine on the intestine of the anesthetized cat may be seen in Figure 45. Wilkinson (1932) found that the effect of acetylcholine on gastric secretion was uncertain and less pronounced than that of histamine.

Glandular Actions. The secretory activity of all gland cells receiving cholinergic innervation is enhanced by the muscarinic action of acetylcholine, an effect quickly and completely abolished by atropine. In man, the salivary, lacrimal and sweat glands are particularly stimulated and the effects produced comprise some of the major objective features of the response to intravenously administered acetylcholine.

Respiratory Actions. Effective doses of acetylcholine cause bronchospasm and increased secretion of the bronchial glands. Heymans and coworkers (1936) describe hyperpnea and tachypnea resulting in dogs from the effect of acetylcholine on the chemosensitive receptors of the carotid sinus. Schweitzer and Wright (1938) have analyzed the effects of acetylcholine on respiration in cats. The drug causes a "triple" response consisting of initial stimulation, subsequent depression and secondary stimulation. It was also found by these investigators that acetylcholine stimulates the chemoreceptors in the carotid sinus and aortic arch. The inhibitory effects appeared due to a direct action of the chemical on the respiratory center and spinal cord. In man, some inspiratory difficulty and cough may result from intravenous injection of large doses. The symptoms are transient, readily blocked by atropine and are unimportant except in patients inclined to have asthmatic attacks.

Miscellaneous Effects. When acetylcholine is injected into the carotid artery, as has been done in man by Battro and Lanari (1937), temporary apnea and homolateral facial vasodilatation and sweating, lacrimation and miosis may be observed. The nicotinic action of acetylcholine in skeletal muscle in man is not observed unless the drug is injected into patients with myasthenia gravis. Under these circumstances, recovery of muscle power is demonstrable (Fraser and coworkers, 1937). Applied locally to the eye, acetylcholine is not miotic unless strong concentrations are used (five per cent solution) accompanied by massage (Molitor, 1936).

Therapeutic Uses

Although acetylcholine has been studied pharmacologically since 1906, no attempt was made to use it or other esters of choline in therapeutics until Villaret and Justin-Besançon (1928, 1929) employed acetylcholine in a wide variety of diseases. It was quickly recognized, however, that the transient and variable effects of acetylcholine make it unsuitable for clinical use, especially when sustained action is desirable, and other choline esters have been substituted for it. Acetylcholine, however, has been employed for a number of diseases, particularly those of blood vessels. Thus it has been tried in *Raynaud's disease, thromboangiitis obliterans, arteriosclerosis obliterans, gangrene, varicose* and *trophic ulcers* and *hypertension*. The drug has also been employed in *scleroderma, arthritis, atonic constipation, paroxysmal tachycardia, lead colic, tobacco amblyopia* and *myasthenia gravis*. In most of these disorders the results obtained have not been encouraging. Kovács and associates (1936) found acetylcholine ineffectual when administered by iontophoresis in the treatment of various peripheral vascular diseases. Abbott (1939), however, has reported successful termination of attacks of *paroxysmal tachycardia* in five patients by the intravenous injection of 100 mgm of acetylcholine. Apparently side-effects were minimal. Likewise, several investigators have reported that hypodermic administration of acetylcholine has produced definite improvement in vision in patients with *tobacco amblyopia* (Orr, 1936; Duggan, 1937; Cragg, 1936). In *myasthenia gravis,* Fraser and coworkers (1937) noted return of muscle power after subcutaneous injection of acetylcholine. Prostigmine, however, is the parasympathomimetic drug of choice.

ACETYL-BETA-METHYLCHOLINE

The unsuitability of acetylcholine for therapeutic purposes stimulated the search for synthetic choline esters which would be more stable in the body and therefore more persistent in their actions. Of more than 200 choline derivatives which have been synthesized and studied, only acetyl-β-methylcholine and carbaminoylcholine are satisfactory for clinical use. Although acetyl-β-methylcholine was studied by Hunt and Taveau as early as 1911, it was not until the systematic investigations of this compound by Simonart (1932) and Starr and associates (1933, *et seq.*) that the drug received adequate therapeutic trial. Major and Cline (1932) first synthesized the compound by a process which makes the drug available in quantity.

A major object of endeavor in the field of synthetic choline esters has been to obtain drugs which would have greater stability and hence more sustained actions in the body. A second objective has been to find derivatives which would be relatively free of nicotinic effects (*i.e.*, actions on sympathetic ganglia and skeletal muscle); but, so far as the clinical use of these compounds is concerned, the second objective is relatively unimportant because the nicotinic actions are not manifested except with large doses under special circumstances. Finally, attempts have been made to find choline esters which would selectively affect certain structures in the body and not others, and hence lend themselves to special fields of usefulness. Whether this goal can be obtained is not yet clear. Clinically, however, the choline esters differ somewhat in the responses they elicit and hence each has been employed for certain fairly definite therapeutic purposes.

Mechanism of Action. Present knowledge indicates that acetyl-β-methylcholine exerts its characteristic effects in the body in a manner similar to that of acetylcholine. The drug is less readily hydrolyzed by cholinesterase than is acetylcholine, and this is the basis for its longer duration of action. Physostigmine and prostigmine, through inhibition of cholinesterase, intensify and prolong the responses to acetyl-β-methylcholine, and atropine quickly and completely abolishes all the muscarinic actions of the drug. The nicotinic properties are less prominent than are those of acetylcholine, and thus it is usually impossible to elicit a rise of blood pressure in an atropinized animal even though large doses of acetyl-β-methylcholine are administered. Responses in skeletal muscle, however, are demonstrable, especially in patients with myasthenia gravis.

Pharmacological Properties

The pharmacological properties of acetyl-β-methylcholine are qualitatively similar to those of acetylcholine, except that the former compound is more stable (Figure 34) and lacks nicotinic effects on autonomic ganglia. Some of the major characteristics of the drug in comparison with allied choline derivatives are shown in Table 19.

Cardiovascular Actions. After adequate doses of acetyl-β-methylcholine, the peripheral vessels dilate, the heart slows and the blood pressure falls. These effects are particularly prominent in anesthetized animals. Small doses of atropine block completely all these cardiovascular responses, but even large doses of the drug do not cause a rise in blood pressure in an atropinized animal similar to that seen after acetylcholine. The bradycardia induced in anesthetized cats and isolated hearts by acetyl-β-methylcholine is blocked by quinidine in a manner similar to that mentioned for acetylcholine, and quinidine also antagonizes the prolongation of auriculoventricular conduction produced by acetyl-β-methylcholine in intact animals (Starr, 1936). Hoff and Nahum (1934) found that the ventricular rhythms produced in cats by epinephrine could be abolished by acetyl-β-methylcholine, and that the ventricular fibrillation following electric shock could be prevented by prior administration of the drug, although auricular fibrillation still appeared (Hoff and Nahum, 1935).

The coronary arteries were found by Wedd (1936) to respond to acetyl-β-methylcholine by primary vasodilatation followed by vasoconstriction, in a manner similar to that noted for acetylcholine, but the latter drug was the more active of the two. In the intact dog, acetyl-β-methylcholine tended to cause a decrease in coronary flow. Katz and associates (1938) noted that the drug caused coronary vasoconstriction in isolated perfused cat hearts but in dog hearts only vasodilatation occurred. The physiological significance of the results obtained by Katz and coworkers in dog hearts with choline esters in regard to the effects of nerve impulses on the caliber of the coronary arteries has been mentioned (page 353). Essex and coworkers (1940), employing trained unanesthetized dogs and the thermostromuhr technic for measuring coronary circulation, found that acetyl-β-methylcholine produced a marked increase in coronary blood flow.

In man, Weiss and Ellis (1934) compared the effects of constant *intravenous* infusion of varying doses of acetylcholine and acetyl-β-methylcholine (Figure 34). The symptoms and signs produced were identical with those described for acetylcholine, but the effective doses were approximately only $\frac{1}{200}$ as large. Thus, a dose of 0.1 mgm per minute caused minimal effects and a dose of 0.4 mgm per minute approached the limit of tolerance. Symptoms disappeared within one minute after the injection was terminated, and there was no evidence of cumulative action. Starr and associates (1933) investigated the effects of acetyl-β-methylcholine given *subcutaneously* and *intramuscularly* to normal subjects. Typical responses observed after a dose of 20 mgm are charted in Figure 35, and it will be noted that a transient fall in blood pressure and a compensatory tachycardia occurred, being less persistent than salivation and sweating. The tachycardia was often replaced by a cardiac rate slower than that present in the control period. Arrhythmias were not encountered. The flush, as a rule, was confined to the emotional blush area. With larger doses, the flush may spread over the chest and trunk (rarely below the umbilicus) and also to the arms and legs. In hypertensive individuals, Page (1935) noted that the flushing as well as sweating did not include the hands and feet. The acute stage of action of the drug lasts only two or three minutes, all the effects vanishing within 15 to 20 minutes.

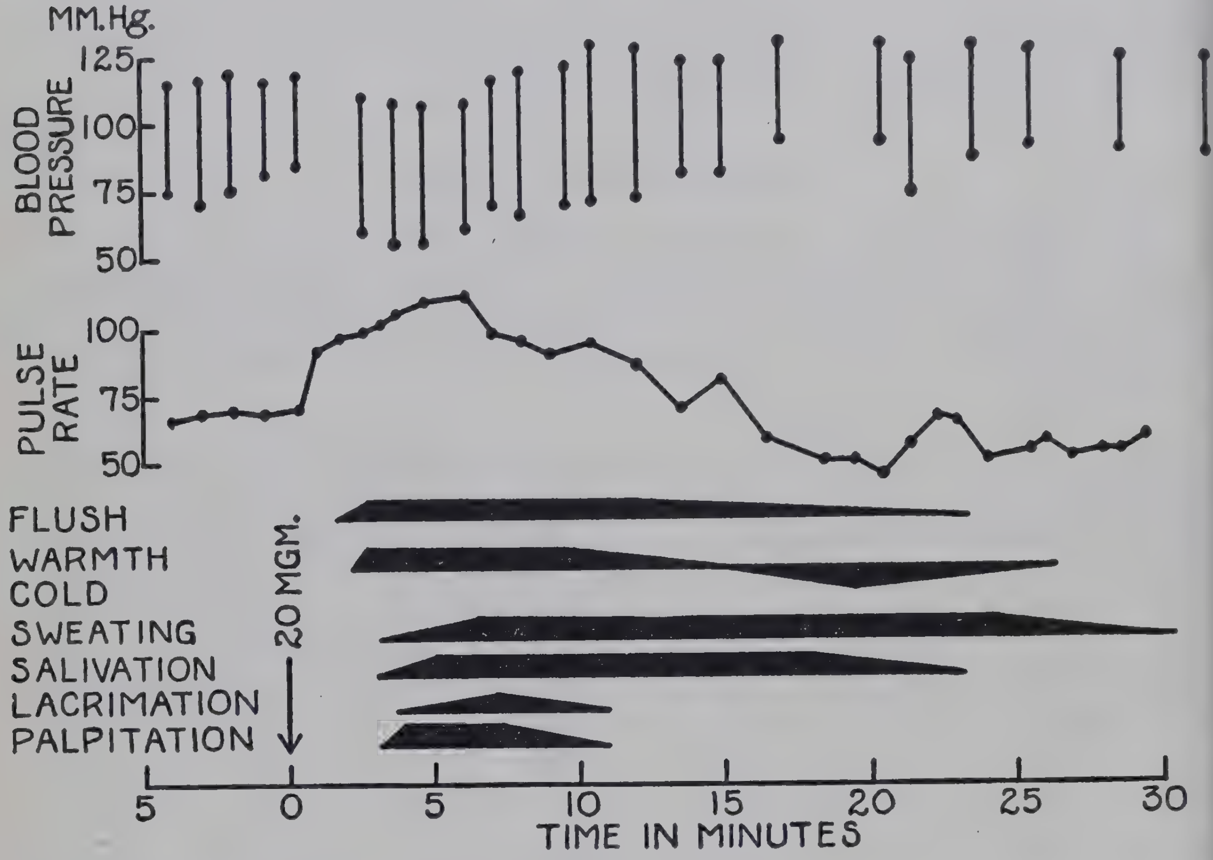

FIGURE 35. *The effect of acetyl-β-methylcholine in man.*

Normal young adult, recumbent posture, 20 mgm of acetyl-β-methylcholine chloride injected subcutaneously at zero time after a preliminary rest period. Note that the first evidence of action of the drug—fall in blood pressure, rise in pulse rate, flushing and a sensation of warmth—appears within one minute. After three minutes, salivation, lacrimation, sweating and palpitation occur and soon reach their maximal intensity. The cardiovascular responses are transient and a bradycardia develops when the blood pressure returns to normal. Chilliness is complained of by subjects who feel warm during the flush. Complete recovery is attained within 15 to 20 minutes after the injection. Additional signs and symptoms are described in the text. Compare this figure with the responses to carbaminoylcholine charted in Figure 37. (After Starr, Elsom, Reisinger and Richards, 1933. Courtesy of the *American Journal of the Medical Sciences.*)

When acetyl-β-methylcholine was administered *orally,* Starr and associates (1933) observed that doses from 50 to 100 times as large as the effective subcutaneous doses had to be employed before noteworthy effects were observed, and these were slow and gradual in onset and mild in character. For example, after a dose of one gram, the blood pressure fell, the diastolic more markedly than the systolic, the pulse rate slowed, the typical flush appeared, and occasionally the skin temperature of the extremities rose, indicating vasodilatation. Arrythmias were not observed and the cardiac output was unaffected.

The ability of acetyl-β-methylcholine to cause *peripheral vasodilatation* and an increase in skin temperature was also studied by Goldsmith (1936), who administered the drug orally to a large group of individuals in doses of from 50 to 1500 mgm. She observed that the skin temperature of the digits often rose six degrees C. or more, vasodilatation being more marked, with a given dose, in the hands than in the feet and greater in patients with vascular spasm than in those with organic occlusion. Those with thromboangiitis obliterans or arteriosclerosis required doses of from 1.0 to 1.5 grams, but patients with vascular spasm sometimes responded to doses of from 50 to 100 mgm. No untoward effects were observed from repeating even the large amounts three times daily, and the changes in blood pressure and pulse rate were insignificant. On the other hand, in hypertensive patients to whom adequate doses of the drug were administered orally or subcutaneously, Page (1935) could detect no increase in skin temperature of the hands and feet despite other evidences that the compound was acting.

In patients with essential or nephritic hypertension, small doses of acetyl-β-methylcholine (2.5 mgm subcutaneously) have been found to cause a moderate to marked decrease in blood pressure whereas the same dose has only a slight effect in normal persons, the percentile fall in pressure averaging three to four times that which occurred in normal controls (Engle and Binger, 1939). Even in those hypertensive patients whose blood pressure had decreased to normal during the control rest period, a greater percentile fall occurred, indicating that the disease itself and not the absolute level of the high blood pressure is the important factor conditioning the decrease in tension noted after the drug. It was also observed that the cold pressor response in hypertensive patients was reduced by the prior administration of acetyl-β-methylcholine. Apparently the peripheral vessels in patients with hypertension respond to the drug with a proportionally greater dilatation than do those of normal persons. Occasionally, the fall may be marked, and Page (1935) records the case of a hypertensive patient whose blood pressure fell from 210/140 to 96/70 after a 20 mgm subcutaneous dose of the compound. Large oral doses (four grams daily) produced either slight and variable reduction or no significant change of the blood pressure of hypertensive subjects. In artificial hypertension induced in human subjects by benzedrine, Loman and coworkers (1939) observed that acetyl-β-methylcholine given by iontophoresis produced a definite fall in blood pressure. In patients with senile hypertension, the choline ester given by the same technic was rarely effective unless preceded by an injection of prostigmine.

The combined administration of acetyl-β-methylcholine and prostigmine may cause *cardiac arrhythmias*. Thus Myerson and associates (1937) observed that the subcutaneous injection of 20 mgm of the choline ester following 0.5 mgm of prostigmine may result in various degrees of severe heart block, and even complete auriculoventricular dissociation. Atropine prevents or abolishes the block. Nahum and Hoff (1935) also observed disorders of cardiac rhythm in patients receiving acetyl-β-methylcholine. In four patients with hyperthyroidism, large doses of the drug (0.75 mgm per kg) produced transient auricular fibrillation. In one patient with auricular flutter and a 2:1 block, acetyl-β-methylcholine induced transient auricular fibrillation with a very slow ventricular rate. Flutter of the auricles did not appear in passing to or from fibrillation. The drug also caused alterations in the ventricular complexes and displacements of the ST segments. The ability of the choline ester to cause a brief period of auricular fibrillation in cats receiving electrical stimulation has been mentioned. Nahum and Hoff believe that auricular fibrillation in these cases is caused by a combination of cholinergic stimulation of the auricle plus an excitant factor, such as thyroxin, electric shock or possibly auricular distention. Page (1935) observed that doses of 10 mgm of acetyl-β-methylcholine injected subcutaneously in patients with hypertension often caused inversion of the T waves of the electrocardiogram in all three leads. Atropine quickly restored the T waves to the upright position. One gram oral doses in the same patients caused no such electrocardiographic change.

Gastro-Intestinal Actions. Acetyl-β-methylcholine in moderate doses causes an increase in tone, amplitude of contraction and peristalsis of all parts of the gastro-intestinal tract (Comroe and Starr, 1933; Molitor, 1936; and others). Vomiting and defecation may occur after larger doses. The drug is a powerful gastric secretogogue and causes an outpouring of acid and pepsin (Gray and Ivy, 1937; Goodman, 1938; Necheles and coworkers, 1938; and others). The gastric secretory response obtained from small doses in dogs with isolated stomach pouches is exactly the same as that charted for carbaminoylcholine in Figure 36. Pancreatic secretory flow apparently is not increased. Atropine counteracts all the motor and secretory gastro-intestinal effects of acetyl-β-methylcholine.

In man, Starr and associates (1933) observed that the subcutaneous injection of 2.5 to 20 mgm of the drug occasionally caused enhanced peristalsis, increased bowel movements and slight nausea. After oral administration, more marked effects were noted and doses of one gram regularly caused increased peristalsis and more frequent defecation. Abbott (1933), in a further study of the actions of acetyl-β-methylcholine on the gastro-intestinal tracts of normal persons by means of balloon and roentgenographic methods, found that the effects on gastric motility varied with the physiological condition of the stomach, contractions being diminished when the stomach was empty and tonus and peristalsis being enhanced when food was present. Both the small and large intestines were stimulated by average subcutaneous doses of the drug. An increase in gastric secretion tended to occur, especially in patients with hypochlorhydria. Oral administration of suitably large doses elicited the same gastro-intestinal responses as did subcutaneous injections of the drug.

Respiratory Effects. Acetyl-β-methylcholine causes bronchoconstriction and increased secretion of the glands of the respiratory mucosa. Both atropine and epinephrine overcome the bronchospasm. In man, Starr and associates (1933) observed that subcutaneous injection of the drug caused no significant effect on respiration except a transitory increase in the depth of breathing. No râles were noted, although in some patients coughing occurred. Occasionally, a sensation of "pressure" or "constriction" under the sternum was complained of, perhaps attributable to bronchospasm, or to spasm of the cardia or esophagus. In one of their subjects, an attack of typical bronchial asthma immediately followed the injection of the drug. Inquiry revealed that this subject had a history of asthma. Oral administration of acetyl-β-methylcholine produced no changes in respiration in any of the persons studied. Hurtado and Kaltreider (1934) observed that the subcutaneous injection of 15 mgm of the drug in two normal young adults decreased the vital capacity between 15 and 20 per cent, at the height of action, the decrease affecting chiefly the complementary air. A sense of substernal constriction was noted by both patients.

Glandular Effects. All glands innervated by cholinergic nerves are stimulated by acetyl-β-methylcholine, and therefore lacrimation, salivation and sweating are prominent objective manifestations of the action of the drug. The secretory responses noted in man after a subcutaneous injection of 20 mgm are charted in Figure 35. Sweating is often so pronounced that the underclothing becomes drenched and the normal rate of salivary flow may be increased ten-fold or more. Sweating and salivation, but not lacrimation, occur after large oral doses and are much less prominent than after parenteral injection. The general and local sweating responses of human beings to acetyl-β-methylcholine have also been investigated by Myerson and associates (1937). They found that the generalized sweating caused by subcutaneous administration of the drug was inhibited by atropine and enhanced by prostigmine or eserine. The local sweating response induced by intradermal injection of acetyl-β-methylcholine is likewise inhibited by atropine but also by epinephrine, as a result of the vasoconstriction caused by the latter drug. The local sweating response varied considerably in different individuals. The sweat produced was alkaline to litmus and the alkalinity increased as the response proceeded. In hypertensive patients, Page (1935) noted that the sweating and flushing, which always occurred in the same areas and paralleled each other in intensity, did not extend to the hands and feet. The clinical investigations of List and Peet (1938) on the sweating mechanism of patients with various types of sympathectomies and peripheral nerve lesions and their diaphoretic response to pilocarpine and acetyl-β-methylcholine are presented on page 390.

Urinary Tract. The general vasodilatation which follows administration of acetyl-β-methylcholine to animals does not extend to the renal vascular bed (Comroe and Starr, 1933), both kidney and urine volume being diminished. The detrusor muscle of the urinary bladder is caused to contract by acetyl-β-methylcholine. In cats with neurogenic bladders due to experimental lesions of the sacral roots and spinal cord, Levin (1938) demonstrated satisfactory evacuation of the bladder following injection of the drug.

In six patients with normal urinary tracts, the effects of acetyl-β-methylcholine were investigated by Loman and coworkers (1938) by means of urographic studies. Given subcutaneously in doses of 20 mgm, the drug caused the kidney shadow to diminish as much as three to four cm. in size. The pelves and calyces became narrowed, the ureters were constricted and showed marked peristalsis and the bladder was contracted markedly, triangular in shape with flattened top and evidenced increased trabeculation. Prostigmine in doses of 0.5 mgm was ineffective but enhanced the urinary effects of small doses of the choline ester so that five mgm of the latter produced the responses listed above.

Miscellaneous Actions. Acetyl-β-methylcholine has practically no effect upon the size and shape of the human *gall bladder* when administered subcutaneously in adequate doses. Indeed, in the majority of cases, the drug causes an inhibition of normal emptying of the gall bladder following the ingestion of a fat meal (Schube and coworkers, 1938). In anesthetized cats, large doses of the ester cause an increase in intrabiliary pressure (Flexner and associates, 1938), but this may be secondary to contraction of the duodenum at the point of entrance of the common bile duct. The *cerebrospinal fluid pressure* is elevated in man after subcutaneous injection of acetyl-β-methylcholine (Myerson and coworkers, 1937), probably a result of the cerebral vascular dilatation. *Skeletal muscle* power is enhanced by administration of acetyl-β-methylcholine to patients with myasthenia gravis (Fraser and coworkers, 1937).

Chemistry and Preparations. The structural formula of acetyl-β-methylcholine is presented on page 351. Its close chemical relation to the other choline esters is evident as well as its relation to muscarine. The drug is available as the chloride or bromide salt.

Acetyl-β-methylcholine Chloride (*Mecholyl; Mecholin*). This compound is not official and is not described in N.N.R. (*see* Report of the Council, 1935). It consists of a white, odorless, bitter, and very deliquescent crystalline powder which is very soluble in water and alcohol. It is decomposed by alkalis. Aqueous solutions are fairly stable to heat and deteriorate slowly on standing. The drug should be kept in tightly stoppered containers. Market preparations include sterile ampules containing 25 mgm each of the dry powder, and sealed vials containing either one or 10 grams of the drug.

Acetyl-β-methylcholine Bromide (*Mecholyl Bromide*). This compound is not official and is not described in N.N.R. It consists of a white, bitter, deliquescent powder which is very soluble in water and alcohol. It is decomposed by alkalis but is fairly stable in aqueous solution. The drug is marketed for oral use in tablets containing 200 mgm each.

Routes of Administration and Doses. *Oral.* In sharp contrast to acetylcholine which is inactive by mouth, large doses of acetyl-β-methylcholine have mild systemic effects when taken orally. The responses appear in from 15 to 75 minutes and are manifested chiefly on the gastro-intestinal tract and peripheral blood vessels. The effective oral dose varies considerably, and although the initial dose is from 50 to 100 mgm, repeated several times daily, amounts as large as 500 mgm to 1.5 grams may have to be given to obtain demonstrable effects. It is apparent that these doses are enormously higher (50 to 100 times higher) than the effective hypodermic dose, due to the destruction of the drug by the gastro-intestinal enzymes and the alkalinity of the intestinal contents. For this reason, oral administration is often unsatisfactory, and the results obtained may be capricious and undependable. Epigastric distress and nausea due to local gastric irritation are usually avoidable by giving the drug in milk.

Subcutaneous. This is the preferred route of administration of acetyl-β-methylcholine for most purposes. The drug is given in aqueous solution and the dose depends on two factors, the results desired and the patient's age. As a rule, the older the patient the larger must be the dose in order to obtain a given effect. The range of dosage varies from 2.5 to 40 mgm or more. It is highly advisable to test the patient's reaction to the smaller doses before resorting to larger ones. When giving the drug by the subcutaneous route, three methods are available for controlling the results obtained with any given dose. First, massage of the site of injection will greatly facilitate absorption. Secondly, a tourniquet applied to the site of injection will delay absorption and allow rapid recovery from effects of the drug which are untoward or greater than desired. Thirdly, the intravenous injection of from 0.5 to 1.0 mgm of atropine will arrest completely and immediately all the muscarinic responses to acetyl-β-methylcholine, and it is recommended that a sterile solution of atropine be kept at hand ready to inject in an emergency. By the methods suggested above, one can control the intensity of action of acetyl-β-methylcholine with a nicety rarely possible with other drugs.

Iontophoresis. In the therapy of peripheral vascular disease, chronic ulcers, arthritis, etc., acetyl-β-methylcholine may be administered by iontophoresis. The drug, like alkaloids, takes a positive electric charge and can thus be carried into the tissues if it is applied to the positive electrode of a galvanic current. For this purpose, an aqueous solution of 0.25 to 1.0 per cent is used to wet an asbestos or cotton pad placed under the positive electrode (malleable metal plate) of a galvanic machine (not diathermy). The dispersive electrode may be applied to the back, a large moist pad being suitable. A current of from 20 to 50 milliamperes is employed for from 20 to 30 minutes, both starting and stopping of the current being performed gradually. The drug should not be applied directly over an ulcerated area of the skin until a firm scab has formed over it. Treatments are usually given two or three times weekly. General reactions are similar to those observed after subcutaneous administration of the drug and can be controlled by reduction of the intensity of the current. Local effects at the site of application of the solution of acetyl-β-methylcholine include warmth, flush, sweating, elevation of skin temperature, and punctate rash, occasionally resembling rose spots. The special technic and apparatus necessary for iontophoresis usually place the procedure beyond the scope of the general practitioner.

Nasal. Systemic effects have been observed in man from the application of strong solutions (25 per cent) of acetyl-β-methylcholine to the nasal mucosa (Van Dellen, Bruger and Wright, 1937), but this route of administration is reserved for the treatment of local affections of the nasal mucous membranes (*e.g.*, ozena).

Clinical Toxicity. A number of the untoward reactions seen clinically after the administration of acetyl-β-methylcholine have been mentioned, but they may profitably be summarized here. Death has not been reported from use of the drug. In one case, a dose ten times the therapeutic gave an alarming but transient syncopal reaction with cardiac arrest and loss of consciousness. In another instance, a full therapeutic dose by error was given intravenously and cardiac asystole occurred for 70 seconds. Complete recovery ensued although the electrocardiogram remained very different from that present before the accident. Nausea and vomiting are usually the first signs of overdosage. Asthmatic attacks may be precipitated, especially in those individuals susceptible to asthma. For example, in 15 asthmatic patients injected subcutaneously with from 20 to 40 mgm of acetyl-β-methylcholine, Villaret and coworkers (1934) noted the occurrence of typical asthmatic attacks in all instances. Substernal pressure or pain has been reported, but whether it is due to bronchoconstriction or spasm of the esophagus or cardia is not known. It seems unlikely that the pain is due to coronary vasoconstriction. Dyspnea may also develop, but it is transient and of no consequence. Fainting may occur if the patient assumes a vertical position during the height of action of the drug. Involuntary defecation may be noted after large doses. Transient complete heart block has been recorded and in individuals with hyperthyroidism the compound has been known to produce a short period of auricular fibrillation. Patients with hypertension may react to the drug with a precipitous fall in blood pressure. Chronic toxicity does not ensue from repeated use of the drug.

Treatment consists of the injection of atropine (0.5 to 1.0 mgm) intramuscularly or intravenously, dependent on the urgency of the case. The patient should be kept recumbent. If an asthmatic attack persists, epinephrine may be needed. Avoidance of most toxic side-actions can be achieved by observing the contraindications and precautions listed.

Contraindications and Precautions. Acetyl-β-methylcholine should never be given by the intravenous route. The dose varies with age, and young adults are quite susceptible to the effects of the drug. Large doses should not be employed until smaller amounts have proved ineffective. Acetyl-β-methylcholine should not be combined with eserine or prostigmine unless there is some impelling reason for doing so and unless the dose of each has been reduced. For example, the prior administration of 0.5 mgm of prostigmine allows five mgm of the choline ester to elicit an intensity of response usually observed only after doses of 20 to 25 mgm. The ester should be given with considerable caution, if at all, to patients with a history of asthma. A sterile solution of atropine should be kept at hand ready for immediate injection if untoward reactions occur which necessitate antidotal therapy. The administration of the drug by iontophoresis should be undertaken only by those thoroughly acquainted with the technical aspects of the procedure. Patients receiving injections of acetyl-β-methylcholine should be in bed and lying down. A bed pan should be provided in the event that the drug makes it necessary to defecate, because assumption of the erect posture during the height of drug action is likely to result in fainting. Hyperthyroid patients should not receive acetyl-β-methylcholine because of the possibility that auricular fibrillation may occur.

Therapeutic Uses

Therapeutic applications of acetyl-β-methylcholine have made use chiefly of the cardiovascular and gastro-intestinal actions of the compound. Thus the drug has been employed successfully in paroxysmal auricular tachycardia, in certain peripheral vascular diseases and in patients with intestinal distention. However, a variety of other uses has received clinical trial.

Disorders of Cardiac Rhythm. *Paroxysmal Tachycardia.* In some patients, reflex vagal stimulation, as, for example, through the carotid sinus mechanism, ocular pressure or the induction of emesis, has long been known to be capable of arresting attacks of paroxysmal tachycardia of auricular or supraventricular origin. Similarly, a large number of such attacks may be relieved quickly by the use of acetyl-β-methylcholine. The most extensive clinical investigations of the efficacy of the drug in this type of arrhythmia have been conducted by Starr (1933, 1936). He was able to bring the attack to an abrupt end in 66 (88 per cent) of 75 attacks in 37 patients. Alternate pressure over the carotid sinus is first performed, a procedure effective in about one-third of the patients. If this is unsuccessful, acetyl-β-methylcholine is administered subcutaneously. The patient should be in bed and forewarned that he may experience deep breathing, warmth, sweating, salivation, intestinal hyperactivity, etc. A bed pan and atropine should be at hand. The dose is adjusted according to both age and weight. Whereas a young adult may respond successfully to 15 to 30 mgm of the drug, an individual over 50 years of age may require from 40 to 50 mgm or more in order to establish normal rhythm. This is evidently related to the ability of the heart to respond to cholinergic stimulation, a phenomenon also noted with regard to atropine. Obese patients require larger doses than do slender ones. If quinidine is being prescribed for the disorder, the choline ester will not revert the rhythm to normal unless the dose of the former drug is small and the dose of the latter large.

If the arrhythmia does not cease promptly at the height of the flush after the administration of the drug, the injection site should be massaged vigorously and the carotid sinuses alternately compressed. Failure to employ these auxiliary measures decreases markedly the percentage of successes. If the disorder persists, a second injection may be given as soon as the effects of the first have subsided, that is, in about twenty to thirty minutes. The second dose is increased and pressure on the carotid sinus is exerted at the height of action of the drug, as denoted by the facial flush. The attack is usually terminated within a minute or two after the drug is injected. The transition period between the paroxysmal tachycardia and the establishment of normal sinus rhythm is characterized by a brief cardiac pause, followed by a momentary irregularity of the rhythm and intensity of heart sounds and of the pulse. Side-effects from acetyl-β-methylcholine are usually slower in appearing and milder in character in patients with paroxysmal tachycardia than in normal persons receiving the same dose (Starr, 1933).

Acetyl-β-methylcholine is useful only to terminate and not to prevent the occurrence of attacks of paroxysmal tachycardia. For the latter purpose, quinidine is the agent of choice. Although acetyl-β-methylcholine produces side-effects disagreeable to the patient, the temporary discomfort is a small price to pay for the relief the drug brings from the distress of the attack. Repeated use of acetyl-β-methylcholine does not impair its efficacy. For example, Wright (1938) reported that the drug (in doses of five to 40 mgm) was immediately successful in stopping 15 of 16 attacks of paroxysmal tachycardia of auriculoventricular nodal origin recurring in a child over a two year period.

Other Arrhythmias. In *auricular flutter,* the ester is rarely successful in restoring the rhythm to normal. The flutter may be converted to auricular fibrillation (Nahum and Hoff, 1935; Starr, 1936) either before or without a return to a normal sinus mechanism. Although the grade of block is often increased and the ventricular rate thereby slowed, the improvement usually is transitory and passes with the subsidence of the action of the drug. However, the differential diagnosis between paroxysmal tachycardia and certain cases of auricular flutter can occasionally be made by taking an electrocardiogram at the height of action of acetyl-β-methylcholine and observing the arrhythmia when the auriculoventricular block is obvious. In patients with *auricular fibrillation,* acetyl-β-methylcholine does not restore a normal sinus mechanism. The ventricular rate may be slowed temporarily but this is of no therapeutic significance. The drug is contraindicated in *tachycardia secondary to hyperthyroidism,* does not slow the rate, may even increase it, and occasionally produces transient fibrillation of the auricles.

Peripheral Vascular Diseases. The effects of acetyl-β-methylcholine on the peripheral vessels and skin temperature have already been described. Attempts have been made to utilize these actions in the therapy of a variety of peripheral vascular diseases. For this purpose, it is necessary to administer the compound in such a manner as to obtain maximal effects on the peripheral vessels for long periods of time and unassociated, if possible, with untoward actions on other functions of the body. Thus, the drug is administered either orally or by iontophoresis.

In *Raynaud's disease,* Starr (1933) studied the response to acetyl-β-methylcholine in four patients. He found that the drug did not prevent the development of vascular spasm when the hands were exposed to severe cold, and did not cause prompt relaxation of the spasm so produced. However, it was capable of overcoming or preventing spasm induced by moderate exposure. In three patients to whom the drug was given orally in doses of from 20 to 100 mgm or more three times daily, a definite measure of relief was experienced from spasm encountered by exposure to cold or during their usual occupations. Striking benefit in 12 patients with Raynaud's disease was obtained by Kovacs and associates (1936) as a result of local iontophoresis. Increased warmth, improved color of the hands and feet, a decrease in the number and severity of attacks during the winter months, and complete healing of painful ulcerations were observed. The syndrome definitely improved despite the complicating factor of scleroderma in six patients.

In patients with *thromboangiitis obliterans* or *arteriosclerosis obliterans,* the organic occlusion of the peripheral vessels precludes great beneficial effect of acetyl-β-methylcholine unless there is an associated factor of vascular spasm. Kovacs and coworkers (1936) thus noted that only those individuals with an appreciable factor of vasospasm responded satisfactorily to therapy with the choline ester, and in these patients there was observed healing of ulcerations and increased exercise tolerance before the appearance of claudication. Starr (1933) found that oral administration of the drug in doses of from 200 to 500 mgm relieved pain and promoted healing in areas of threatened gangrene in at least two of four patients with occlusive peripheral vascular disease. The subcutaneous route is contraindicated, and large oral doses may be needed before relief is obtained. In all cases of thromboangiitis obliterans, Kramer (1937) observed that iontophoresis with acetyl-β-methylcholine resulted in definite improvement in three, some benefit in three, temporary relief in two and failure in three. In eight patients with diabetes mellitus and peripheral arteritis, five showed improvement.

Other disorders related to the integrity of the peripheral circulation have been reported to show improvement after therapy with acetyl-β-methylcholine. These include *phlebitis, varicose* and other *ulcers,* etc. (Starr, 1933; Kovacs and associates, 1936; Kramer, 1937; and others). Saylor and associates (1936) have had particularly successful results in patients with chronic varicose ulcers, healing occurring in 23 of 26 consecutive unselected patients, and they recommend iontophoresis therapy for those ulcers occurring in patients in whom sclerosing injections are contraindicated or have failed, as, for example, in persons with phlebitis or diabetes.

Gastro-Intestinal Disorders. Acetyl-β-methylcholine has been successfully employed in patients with *abdominal distention* due to postoperative intestinal ileus, anesthesia, acute infectious diseases, etc., although the advent of prostigmine has decreased the frequency of its employment. It is administered by the subcutaneous route in doses of 10 to 20 mgm (Abbott, 1933). Pain may be exaggerated temporarily due to resumption of intestinal activity, and insertion of a rectal tube may be necessary to permit expulsion of the gas. Occasionally, the drug acts when other measures such as an inlying rectal tube, medicated enemas, hot fomentation, turpentine stupes, prostigmine, posterior pituitary, etc., have failed; but it is probably best to reserve its use for patients in whom the more usual and milder procedures have been tried.

In patients with *atonic constipation,* the oral use of large doses of acetyl-β-methylcholine may allow comfortable laxation and a satisfactory increase in the frequency of stools. The drug has also been administered orally with promising results to children with *megacolon* (Law, 1940). Similarly, the drug may be employed to test the functional ability of the musculature of the colon prior to surgical intervention in cases of congenital megacolon.

Urinary Tract Disturbances. Acetyl-β-methylcholine has been employed to aid evacuation of urine and thus avoid catheterization and the attendant risk of uriniary tract infection in patients suffering from postoperative urinary retention or various neurogenic disturbances of the urinary bladder; but the advent of prostigmine and carbaminoylcholine has decreased the use of the compound for this purpose. Langworthy (1936) has reported favorable effects from administration of acetyl-β-methylcholine in tabes dorsalis, and has been able to reduce residual urines of large volume to practically zero. He also found it to be of value in treating acute urinary retention which may occur in tabetics, especially during malarial therapy. Use of the drug has not yielded striking results in bladder dysfunction due to other forms of nervous system injury.

Miscellaneous Uses. In the therapy of arthritis, a number of investigators have apparently obtained favorable results from iontophoresis with acetyl-β-methylcholine. Treatment is not curative but symptomatic improvement may be obtained in a substantial number of cases. Pain, swelling, stiffness and muscular fatigue are reduced and joint function increased. Kovacs and coworkers (1936) reported a series of 117 arthritics observed for from two weeks to two years, treatment being administered twice weekly on the average. Of 44 patients with osteoarthritis, definite improvement occurred in 31; of 73 with rheumatoid arthritis, 50 patients claimed that they were improved. These workers caution that the results are difficult to evaluate, that spontaneous remissions are frequent, that psychological factors are prominent, and that relapses may occur during the course of treatment. Other investigators reporting favorable results in arthritis include Abel (1935), Mathae (1936) and Boyd and associates (1936). The workers last named observed that failures were more prominent in elderly patients suffering from advanced rheumatic arthritis with bone changes and fibrosis, and that those who gained most from the treatment were patients with accompanying circulatory disturbances of the extremities with cool, pale, moist and often cyanotic hands and feet.

Acetyl-β-methylcholine has been employed for a variety of other diseases and symptoms. Patients with *essential hypertension* do not respond favorably to the drug, and acetyl-β-methylcholine does not fulfill the requirements outlined on page 563. Indeed, the drug may cause untoward reactions in hypertensive individuals. It was mentioned previously that favorable results have been reported in *scleroderma* (Kovacs and collaborators, 1936). Duryee and Wright (1937) have also obtained improvement in their patients and record softening and loosening of the skin, healing of ulcerations, return of sweating and hair to the affected parts and occasionally increased visibility of capillaries. In *myasthenia gravis,* muscle power improves (Fraser and coworkers, 1937), but prostigmine and other measures are to be preferred. In *ozena,* local application of a solution of the drug to the nasal mucosa has apparently afforded relief. Prostigmine has also been employed for a similar purpose. Acetyl-β-methylcholine has also been employed in patients with *Ménière's disease, tobacco amblyopia, glaucoma, migraine, cerebrovascular spasm, post-lumbar puncture headache, acrodynia, hypochlorhydria,* etc., but the rationale is not always evident nor is the alleged improvement always due to the drug.

An interesting diagnostic application of the parasympathomimetic actions of acetyl-β-methylcholine is in the detection of *atropine poisoning* (Dameshek and Feinsilver, 1937). If a patient is suspected of having poisoning due to the belladonna alkaloids, 10 to 30 mgm of the choline ester may be injected subcutaneously. The failure of appearance of the characteristic flush, sweating, lacrimation, rhinorrhea, salivation, enhanced peristalsis, etc., is pathognomonic of belladonna intoxication and the diagnosis can thus be made with certainty in otherwise doubtful cases.

CARBAMINOYLCHOLINE

Carbaminoylcholine is another synthetic derivative of choline. It was first prepared by Kreitmar in 1932 and its pharmacological properties have been investigated particularly by Noll (1932), Dautebrande (1933), Simonart and Simonart (1935), Molitor (1936) and Starr (1937). The drug was introduced into therapeutics as a substitute for acetylcholine and under certain circumstances is to be preferred to acetyl-β-methylcholine.

Chemistry and Preparations. The chemical structure of carbaminoylcholine is shown on page 351, and the relationship between its structure and pharmacological action has already been discussed. The drug is available for clinical use in the form of its chloride salt.

Carbaminoylcholine Chloride (Carbamylcholine Chloride; Doryl; Lentin) is not an official preparation and is not described in the N.N.R. It consists of a white, odorless crystalline powder, stable in air and in aqueous solution even when heated. The drug is soluble in water 1:1 to give a solution neutral to litmus. Carbaminoylcholine chloride is available in tablet triturates for oral use (0.2 and 0.4 mgm) and in hypodermic tablets (0.2 and 0.4 mgm). It is also supplied as a powder for preparation of solutions for application to the conjunctiva or nasal mucosa.

Pharmacological Properties. Carbaminoylcholine is a powerful parasympathomimetic agent and differs from acetyl-β-methylcholine especially in being much more stable in body fluids and possessing nicotinic actions on autonomic ganglia. The drug is not susceptible to destruction by cholinesterase and therefore its activity is neither enhanced nor prolonged by eserine or prostigmine (Figure 33). Although selective affinities of the drug for particular organs are not readily demonstrable in animals (Molitor, 1936), the results obtained from its administration to human beings suggest that the drug has a greater action on the gastro-intestinal tract and urinary bladder and less action on the heart than is the case with acetyl-β-methylcholine. Some of the major characteristics of the drug in comparison with allied choline derivatives are shown in Table 19.

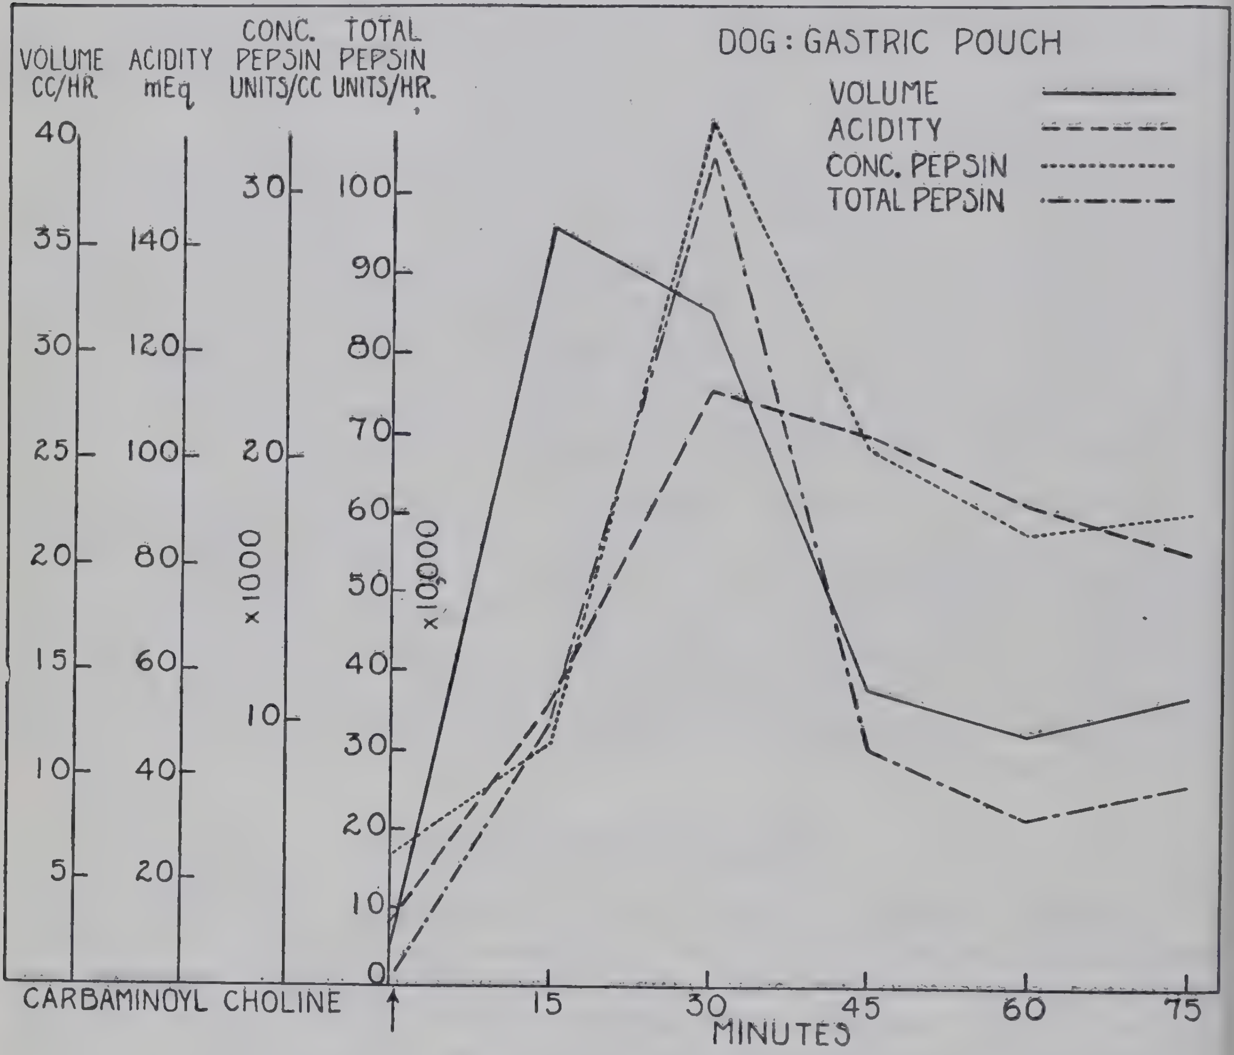

FIGURE 36. *The effect of carbaminoylcholine (doryl) on the gastric secretion of an isolated stomach pouch in a dog.*

Pepsin unitage: one cc of a one per cent solution of 1:10,000 pepsin equals 1000 units. Note factors for multiplication in pepsin scales. A fasting sample was taken at zero time, after which 0.008 mgm of doryl per kilo was injected subcutaneously and samples collected at 15 minute intervals. Note that the secretion of all components of the gastric juice is markedly stimulated, especially pepsin. This response to doryl can be antagonized by atropine.

In *animals,* marked stimulation of all structures innervated by cholinergic nerves occurs as a result of the administration of adequate amounts of carbaminoylcholine. Thus there is seen a fall in blood pressure, bradycardia, peripheral vasodilatation, sweating, lacrimation, salivation, miosis, increased peristalsis, contraction of the uterus and urinary bladder, skeletal muscular stimulation and a rise in blood pressure after atropine (nicotinic action). All the muscarinic effects listed are antagonized by atropine. Carbaminoylcholine is the most potent and also the most toxic of the known derivatives of choline, but its margin of safety in clinical use is practically identical with that of acetyl-β-methylcholine. Inasmuch as carbaminoylcholine is not destroyed by the cholinesterase of tissue and blood, its therapeutic potency and toxicity are not affected by the combined administration of anti-esterase drugs such as eserine and prostigmine. This is in

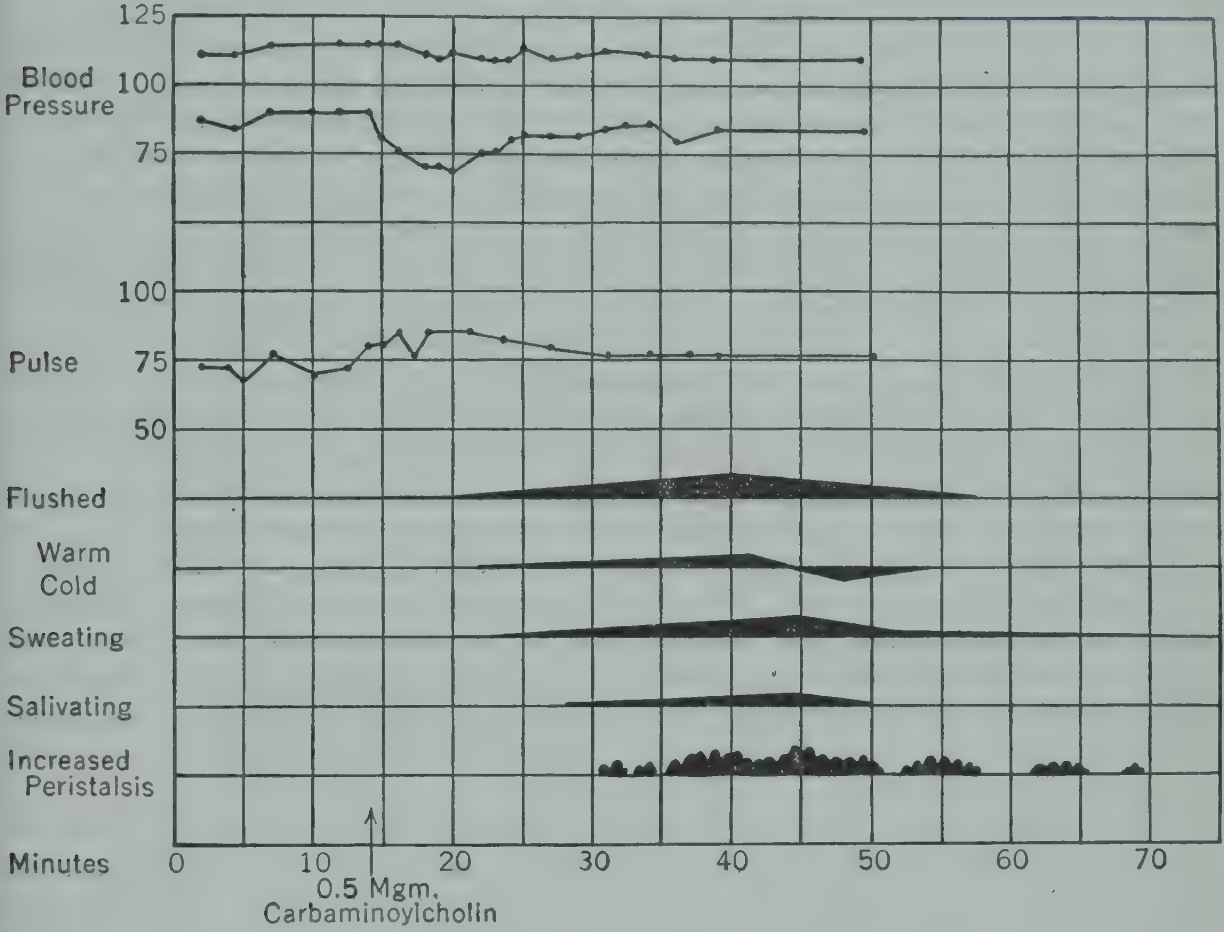

Figure 37. *The effects of carbaminoylcholine in man.*

Normal young adult, recumbent posture, 0.5 mgm carbaminoylcholine chloride injected subcutaneously at zero time after a preliminary rest period. The diastolic blood pressure begins to fall within a minute or two and reaches its lowest level within six minutes, at which time the pulse rate shows its maximal acceleration. These two effects are never marked and recede within the following ten minutes. Flushing, a sensation of warmth, and sweating appear only after six minutes or more from the time of injection, develop gradually and are never as prominent as after acetyl-β-methylcholine. Salivation is even less noticeable. About 15 minutes after the administration of carbaminoylcholine, borborygmus is usually noted, increases in intensity and is sometimes accompanied by cramps. The height of action of the drug is reached in from 20 to 30 minutes, at a time when the effects of acetyl-β-methylcholine would have already disappeared (see Figure 35). The actions wear off gradually and disappear after approximately one hour. See text for the signs and symptoms produced by the drug. (After Starr, 1937. Courtesy of the *American Journal of the Medical Sciences.*)

sharp contrast to acetylcholine and acetyl-β-methylcholine. If the dose is properly selected, certain pharmacological actions can be elicited with doses which do not evoke others. For example, the drug produces marked stimulation of all constituents of the gastric juice in doses which cause few other discernible effects. In dogs with isolated gastric pouches, carbaminoylcholine can readily be shown to be the most potent secretogogue of the choline group of drugs, and in particular it is the most potent peptogogue known (Goodman, 1938). A typical gastric secretory response to the drug is shown in Figure 36.

The effects of carbaminoylcholine in *man* have been studied especially by Starr (1937) who tested the actions of oral (0.4 to 1.0 mgm) or subcutaneous (0.1 to 1.0 mgm) doses in a group of 26 normal young adults. The typical responses elicited by a subcutaneous injection of 0.5 mgm of carbaminoylcholine are depicted in Figure 37, which may profitably be compared with Figure 35. It will be noted that the actions appear more slowly and gradually than after the injection of acetyl-β-methylcholine and last much longer. Warmth and flushing of the face are the first evidence of action of the drug. Sweating, lacrimation and salivation occur later and are not nearly as prominent as after acetyl-β-methylcholine. Audible peristalsis and occasionally intestinal cramps appear after 15 to 20 minutes, and a desire to urinate may be experienced by some subjects. The diastolic pressure often but not always falls slightly and the pulse rate rises somewhat, these effects occurring early. Palpitation and respiratory effects do not ensue. After injection of larger doses (1.0 mgm), the actions still come on slowly and are similar to those outlined above. The blood pressure and pulse changes are not more marked but the remaining actions are prominent, abdominal cramps being so uncomfortable that atropine has to be administered. As a rule, the largest doses which can be tolerated cause severe intestinal effects before the blood pressure is greatly affected. This is in sharp contrast to the actions of acetyl-β-methylcholine which are prominent on the cardiovascular system at a time when the gastro-intestinal effects are still minimal.

Starr also studied the response to *oral* administration of carbaminoylcholine. A dose of 0.6 mgm causes slight effects, manifest after one hour by the appearance of flushing, sweating, epigastric distress, and belching; after two hours by a sensation of tightness in the urinary bladder and still later by some difficulty in visual accommodation. Changes in the pulse rate and blood pressure are slight. Headache, salivation, and abdominal cramps may appear after large doses. Cumulative effects evidently occur from repeated oral administration, probably indicating the resistance of the drug to destruction in the body, and some patients given 0.4 mgm orally three times daily soon complained that the dose was being increased. The majority of persons, however, are able to tolerate from 0.2 to 0.4 mgm orally once or twice daily without difficulty. Still others are able to take much larger doses without untoward effects. It is clear, therefore, that the actions of the drug are variable and uncertain after oral administration, and a dose producing uncomfortable effects in one patient may be well tolerated by another.

In a more detailed study of the cardiovascular and certain other responses to carbaminoylcholine, Starr and associates (1937) gave 0.5 mgm subcutaneously to six patients, four of whom had peripheral vascular disease and previously had experienced relief from pain after the drug. The average results obtained were as follows (+ = increase; — = decrease): pulse rate, +7.6 per cent; systolic blood pressure, —6.5 per cent; diastolic pressure, —7.2 per cent; cardiac output, +12.3 per cent; stroke volume, +3.7 per cent; left ventricular work per minute, +4.9 per cent; left ventricular work per beat, —2.6 per cent; heart volume, —2.0 per cent; metabolic rate, +3.5 per cent; arteriovenous oxygen difference, —5.5 per cent; respiratory volume, +5.6 per cent; peripheral vascular resistance, —16.6. Only the effects on blood pressure, pulse rate and respiratory volume appear statistically significant. The above data do not indicate that carbaminoylcholine has a stimulant or depressant effect on the human heart in the doses employed. Electrocardiographic studies revealed no changes attributable to the drug.

Whereas atropine prevents or rapidly abolishes all the muscarinic responses to acetylcholine and acetyl-β-methylcholine, it acts more slowly and less effectively in antagonizing the actions of carbaminoylcholine. Thus Starr (1937) found that atropine, given subcutaneously to 12 normal subjects in a dose of 0.6 mgm 20 minutes before an injection of 0.3 mgm of carbaminoylcholine, completely blocked the usual effects of the latter drug. The same dose of atropine greatly diminished the response to 0.4 mgm of carbaminoylcholine, had a slight antagonistic effect on the action of 0.8 mgm, but did not significantly alter the response to 1.0 mgm. Likewise, when the full effects of a large subcutaneous dose of carbaminoylcholine were manifest, the injection of 0.3 mgm of atropine did not significantly diminish their intensity. A dose of atropine of 0.6 mgm under these circumstances caused a slow but definite disappearance of the uncomfortable actions within 30 minutes.

Doses and Routes of Administration. Carbaminoylcholine may be administered orally or subcutaneously. The *oral* dose varies from 0.2 to 0.8 mgm two or three times daily, dependent on the patient's tolerance and the results desired. The single *subcutaneous* dose ranges from 0.2 to 0.4 mgm. It will be noted that the oral dose is not much larger than the subcutaneous, in sharp contrast to the ratio of oral and subcutaneous doses of acetyl-β-methylcholine. This is due to the greater stability of carbaminoylcholine in the intestinal fluids. The drug should not be injected intravenously. In weak solution (0.1 per cent), carbaminoylcholine may be applied locally to the nasal mucosa or conjuctiva. A solution of atropine ready for immediate injection should be at hand to counteract untoward responses to the drug.

Clinical Toxicity. Carbaminoylcholine produces the same toxic effects described for acetyl-β-methylcholine but the relative intensity of these varies somewhat. Patients differ considerably in their response to the drug, especially when it is orally administered. Malaise, headache, abdominal discomfort, nausea, belching, peristaltic waves, colicky pain, diarrhea, flushing, a sensation of heat about the face, asthmatic attacks, and fall in blood pressure are among the prominent reactions which are noted. As stated, the gastro-intestinal actions are more prominent than are the cardiovascular actions. The ordinary therapeutic dose of atropine (0.6 mgm) antagonizes the untoward effects of large doses of carbaminoylcholine much more slowly than those of acetyl-β-methylcholine, and increased amounts of atropine may have to be given to obtain relief.

Therapeutic Uses. Carbaminoylcholine has been employed in several of the syndromes for which acetyl-β-methylcholine has been used, but the drug is relatively new and sufficient clinical data are not yet available properly to appraise its clinical status. Particularly promising reports have appeared concerning its use in patients with peripheral vascular disease and urinary retention.

In patients with *peripheral vascular disease,* the administration of carbaminoylcholine often results in increased peripheral circulation, especially when vasospasm rather than organic occlusion predominates. Rest pain may be strikingly relieved and the healing of areas of threatened gangrene promoted. Inasmuch as oral medication is often unsatisfactory, small doses may be given at intervals by injection. Patients who cannot be kept under medical supervision should receive oral therapy with acetyl-β-methylcholine rather than with carbaminoylcholine.

In a number of clinical reports, favorable results have apparently been obtained from the use of carbaminoylcholine in patients with *urinary retention* occurring after surgical operation, childbirth or anesthesia, or that due to lesions of the spinal cord. Thus the necessity for catheterization with the attendant danger of infection may be circumvented. Great care should be exercised in using the drug in patients who are very ill or in shock. The effective subcutaneous dose is usually 0.25 mgm and it may be necessary to repeat this once or twice at half-hour intervals. Evacuation of the bladder usually occurs in from five to 30 minutes (Moir, 1937; Maxwell, 1937; Officer and Stewart, 1937; Schwartz, 1938; and others).

Miscellaneous Uses. Carbaminoylcholine has not been found effective in the treatment of cardiac arrhythmias, and acetyl-β-methylcholine remains the preferred agent for use in paroxysmal tachycardia. Although the drug causes an acute fall in blood pressure in hypertensive individuals, attempts to lower the elevated blood pressure over a prolonged period have been unsuccessful (Starr, 1937). Carbaminoylcholine increases muscular power in patients with *myasthenia gravis* (Fraser and coworkers, 1937), but prostigmine remains the parasympathomimetic agent of choice in this disease. The choline compound has also been employed locally with varying degrees of success in *ozena* and *increased intraocular tension.*

CHAPTER 21

DRUGS STIMULATING STRUCTURES INNERVATED BY CHOLINERGIC NERVES (PARASYMPATHOMIMETIC DRUGS)

II. INHIBITORS OF CHOLINESTERASE: PHYSOSTIGMINE (ESERINE) AND PROSTIGMINE

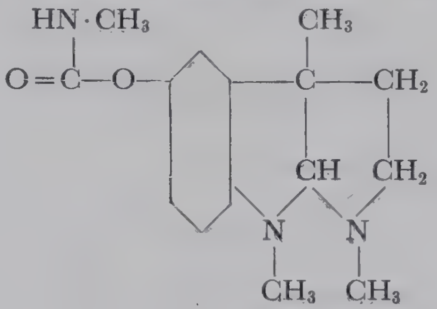
PHYSOSTIGMINE (ESERINE)

History and Source. Physostigmine, also called eserine, is an alkaloid obtained from the Calabar or ordeal bean, the dried ripe seed of *Physostigma venenosum,* a perennial woody climber growing on the banks of streams in tropical West Africa.

These beans were once used by the native tribes as an "ordeal poison" in trials for witchcraft. If the usual symptoms of poisoning developed, the victim was pronounced guilty. It is said that the innocent person, unafraid of the ordeal, would eat the poison rapidly. Vomiting from gastric irritation would ensue and automatic protection was thus afforded. The guilty person, afraid of the trial, would partake slowly of the bean and poisoning rather than emesis would result.

Although the calabar beans were known in England in 1840, their properties were not investigated until a number of years later. In 1863, Fraser noted that extracts of the bean caused pupillary constriction. In the following year, the pure alkaloid, physostigmine, was isolated by Jobst and Hesse. The first extensive studies on the pharmacology of the pure alkaloid were those of Harnack and Witkowski in 1876.

Chemistry, Preparations and Doses. Although several alkaloids have been isolated from the Calabar bean, the most important one is physostigmine. The chemical structure of this substance is as follows:



Physostigmine

The official preparation is *Physostigmine Salicylate (Eserine Salicylate),* U.S.P., B.P., consisting of colorless bitter crystals which are soluble in water (1:75). The salt and its aqueous solutions in glass containers oxidize upon exposure to air and light and turn first a pink and then a reddish-brown color due to the formation of rubreserine. These colored solutions are decomposed and should not be employed. Addition of boric acid will prevent the decomposition. The average adult oral dose of physostigmine salicylate is 2.0 mgm; the hypodermic dose, 0.5 to 1.0 mgm. *Lamella of Physostigmine* is official in the B.P., each disc containing 0.065 mgm of the alkaloid.

The relationship between the chemical structure of physostigmine and its pharmacological properties is discussed under prostigmine.

Mechanism of Action. Physostigmine exerts its pharmacological activity in the body by inhibiting cholinesterase in body fluids and tissues (page 339). This esterase is responsible for the rapid and continuous destruction of acetylcholine, whether the latter is produced physiologically as the result of cholinergic nerve impulses or injected into the body by the physician. Physostigmine preserves acetylcholine from enzymatic hydrolysis and its pharmacological effects may be accounted for on this basis. One may expect, therefore, that the responses to physostigmine would be detectable only in those structures innervated by cholinergic nerves, and that the drug would be inactive in the absence of acetylcholine. Both of these propositions are true.

By preventing the rapid hydrolysis and inactivation of acetylcholine, physostigmine allows the latter to exert, in an intensified manner, all of its characteristic actions. These include not only the muscarinic effects of acetylcholine on smooth muscles, glands and the heart, but also the nicotinic actions of acetylcholine on skeletal muscles and autonomic ganglia. This accounts for the fact that the actions of physostigmine are not always entirely predictable, as are those of muscarine and pilocarpine which possess only muscarinic properties. The effects of physostigmine on ganglia, for example, may antagonize or occasionally supersede those on the more peripheral effector organs. This is particularly evident in the cardiovascular responses to physostigmine. The preservation of acetylcholine by physostigmine peripherally at cholinergic nerve endings in the heart and in smooth muscles of blood vessels will tend to cause bradycardia, vasodilatation and lowering of blood pressure, whereas the same property of the drug exerted in sympathetic ganglia will cause tachycardia, vasoconstriction and an increase in blood pressure. In addition, physostigmine preserves acetylcholine liberated by splanchnic nerve impulses to the adrenal medulla (page 332), and thus increases the discharge of epinephrine. The epinephrine, in turn, antagonizes the muscarinic effects of physostigmine.

When the cholinergic nerves to an organ are resected and degenerate, acetylcholine can no longer be locally liberated as the chemical mediator (page 341). Under these circumstances, physostigmine fails to manifest its characteristic effects. This is clearly seen, for example, in the denervated iris where physostigmine normally causes miosis. Likewise, when skeletal muscle is deprived of its spinal motor innervation, physostigmine loses its ability to cause typical fibrillary twitching. Although cholinesterase is inhibited, there is no substrate (*i.e.*, acetylcholine) to be protected. Under certain circumstances, the administration of physostigmine will produce contraction in denervated skeletal muscle, but in such an instance it is possible to demonstrate that acetylcholine is being produced locally by other cholinergic nerves, namely, the cholinergic vasodilator fibers to blood vessels in the muscle.

It is claimed by some workers that physostigmine, in addition to acting through its anticholinesterase property, also exerts a direct effect on muscle and gland cells. The strongest evidence for this view comes from the studies on the relationship between cholinsterase inhibition and physostigmine action. It has been shown, for example, that after the alkaloid has depressed serum cholinesterase activity to a given low level, additional amounts of drug will continue to cause responses of effector organs proportionate to the dose without further depression of esterase activity. The obvious objection to these experiments, however, is that serum cholinesterase is being studied rather than tissue cholinesterase, and in the last analysis it is the titer of tissue esterase which determines the rate of acetylcholine hydrolysis and the effectiveness of physostigmine. Unfortunately, little is known of the quantitative aspects of the inactivation of tissue esterases by physostigmine.

Atropine prevents the muscarinic effects of physostigmine; curare and nicotine, the nicotinic effects. Theoretically, at least, an atropinized, curarized and nicotinized animal should be completely protected against the responses to physostigmine. These autonomic blocking drugs prevent the effector cells from responding to the acetylcholine preserved by the anticholinesterase action of physostigmine.

Physostigmine Specificity for Cholinesterase. Although a number of drugs and other chemical agents can be shown to inhibit cholinesterase activity, none of these can compare in potency or specificity with physostigmine and related compounds. A number of enzymes exist in the body which are capable of hydrolyzing various esters, but physostigmine and prostigmine selectively inhibit only that enzyme which is concerned with the destruction of acetylcholine, namely, cholinesterase. For example, the injection of one mgm of physostigmine in man reduces the cholinesterase activity of serum by about 15 per cent (Jones and Tod, 1935). In dogs, intravenous physostigmine (0.1 mgm per kg) reduces the activity of the serum esterase almost instantaneously by 75 to 90 per cent (Hall and Ettinger, 1937). Comparable data are available for prostigmine. Physostigmine does not destroy cholinesterase but merely inactivates it temporarily by loosely combining with it. This union can be broken in various ways with a resulting restoration of full enzymatic activity. *In vitro,* this can be accomplished by dialyzing physostigmine free from its combination with cholinesterase. In the body, physostigmine is released from combination with the enzyme by destruction of the drug and by its excretion in the urine.

Pharmacological Actions

In view of the mechanism of action of physostigmine, it should be possible to predict the pharmacological properties of the alkaloid merely by knowing those loci where acetylcholine is physiologically released by nerve impulses and the responses of the corresponding end-organs to the chemical mediator. In the main this is true, but several factors prevent the rigid application of such an assumption. As was stated previously, the final response of autonomic structures to physostigmine depends on the balance between the ganglionic and peripheral components of its action. Again, some organs which respond phasically rather than continuously to nerve impulses will not have a constant supply of acetylcholine to be protected by physostigmine. Also, little is known concerning the esterases in various tissues of the body in health and disease or the relative ease with which they are inactivated by physostigmine. Thus, when a *therapeutic* dose of the drug is given to man, the actions on the pupil and bowel are more prominent than those on voluntary muscle, which may show no reaction. On the other hand, when this same dose is given to a patient with myasthenia gravis, marked therapeutic benefit may be obtained from the effects on skeletal muscle. Finally, physostigmine may act to block ganglia and motor end-plates by preserving acetylcholine to such an extent that the paralyzing phase of the nicotinic actions of acetylcholine is brought into play (page 339).

The main therapeutic effects of physostigmine are concerned with the *pupil, intestine* and *skeletal muscle.* Most of the other responses are mainly of toxicological interest.

Eye. When applied locally to the conjunctiva, physostigmine causes pupillary constriction and spasm of accommodation. The intraocular pressure falls. Miosis is manifest in a few minutes and becomes maximal in one-half hour. The pupil gradually returns to its normal size within a period varying from one day to several days. Although the pupil is pin-point in size after physostigmine and smaller than that normally obtainable by the strongest light, it contracts ever further when exposed to weak light. The spasm of accommodation, which may cause macropia, is rather transient and usually disappears in three hours. The fall in intraocular tension is particularly marked in cases when this pressure is elevated, and results mainly from the miosis, a factor which facilitates the resorption of the aqueous humour.

Gastro-intestinal Tract. Physostigmine increases the tone and motility of the gastro-intestinal tract. Peristalsis is exaggerated and bowel evacuations result. Belching is also common. The secretory activity of the intestinal tract tends to be enhanced, although this effect is naturally not as noticeable as with pilocarpine which stimulates the gland cells directly. The vasoconstriction which may accompany the action of physostigmine would act to reduce glandular secretion.

Skeletal Muscles. In normal persons, therapeutic amounts of physostigmine are without noticeable effect on skeletal muscle. Larger doses, however, cause generalized fibrillary twitchings, the muscles of the eyes, face, tongue, throat and extremities being affected earlier than those of the trunk and limbs. This action, more fully discussed under prostigmine, is not affected by atropine but can be blocked by curare (*see* Briscoe, 1936). After a large dose of physostigmine, the stimulation of muscles may be followed by a curariform depression (Morison and Rosenblueth, 1936). Completely denervated muscles no longer respond to physostigmine, but the action of injected acetylcholine on such muscles is intensified by physostigmine.

Other Actions of Physostigmine. Physostigmine tends to increase the *secretions* of the salivary, lacrimal, mucous and sweat glands but this action is less prominent than that of pilocarpine and muscarine. *Smooth muscles* receiving cholinergic innervation are stimulated, including those of the bronchi, ureters, urinary bladder, biliary ducts and spleen. The contraction of the spleen may cause a temporary increase in the circulating red and white blood corpuscles.

The *cardiovascular effects* of physostigmine are varied. Ordinary doses in man tend to slow the pulse and lower the blood pressure somewhat. This may be followed, especially with doses of two to four mgm, by a mild tachycardia and a rise in blood pressure of 10 to 20 mm of mercury. The ultimate effect of physostigmine on rate, rhythm and force of cardiac contraction and on blood pressure depends not only on the dose of drug and species of animal but also on the several factors outlined. In human beings, the nicotinic effects of physostigmine on cardiac sympathetic ganglia counteract to some degree the muscarinic actions, and thus the marked bradycardia and hypotension observed after muscarine and choline esters are not evident. Furthermore, physostigmine causes the *liberation of epinephrine* from the adrenal medulla and this produces vasoconstriction, tachycardia and a rise in blood pressure. Large doses of physostigmine, however, cause a significant fall in pulse rate and blood pressure.

The quantitative aspects of the *secretion of epinephrine* after the administration of physostigmine are quite interesting. Stewart and Rogoff (1921) found that the epinephrine content of the blood increased to as much as 15 times the normal after physostigmine. Edmunds and Smith (1932) showed that the epinephrine content of the adrenal glands in dogs receiving physostigmine intramuscularly fell within five hours to about one-third of the normal, and that repeated injections over a period of two or more days depleted the glands to about one-eighth of their normal content of hormone.

The effects of physostigmine, prostigmine and a number of closely related anticholinesterase chemicals have been studied for their actions on the *central nervous system* (Schweitzer and Wright, 1937, 1938, 1939; Kremer and coworkers, 1937; Miller and coworkers, 1940). These studies are of great academic interest for they attempt to extend the theory of chemical mediation of nerve impulses from the field of the peripheral autonomic nervous system to that of the brain and spinal cord (page 334). In brief, such investigations have shown that some physostigmine-like drugs tend to facilitate and others to inhibit central synaptic transmission of impulses, and the difference in the two groups of drugs has been related to their chemical structure. It is suggested that those anticholinesterase chemicals which are lipid-insoluble quaternary ammonium compounds preserve acetylcholine outside nerve cells and thus act as curare-like depressants; whereas those which are lipid-soluble tertiary ammonium bases preserve acetylcholine inside nerve cells and thus act as convulsive stimulants. The ultimate implications of these findings cannot be stated. As yet they have no therapeutic importance, and ordinary clinical doses of physostigmine have no significant action on the central nervous system of man. Doses which are larger than usual cause preliminary respiratory stimulation followed by depression, and toxic amounts are mainly depressant to the brain and cord.

Physostigmine Poisoning. The symptoms and signs of poisoning by physostigmine and prostigmine are sufficiently similar to allow a single description to suffice for both drugs. Poisoning from these alkaloids usually occurs accidentally in medical practice. Symptoms come on quickly after ingestion of the drug and soon reach their peak. The effects on the bowel are as a rule first to be noted and violent peristalsis, nausea, vomiting, colic, persistent purging and vomiting occur. The skeletal muscle phenomena consist of fibrillary twitchings all over the body, nystagmus and dysarthria. Restlessness and weakness are prominent. The pupils are pin-point in size and distant objects are blurred. Sweating, salivation and lacrimation may be marked. Dyspnea is present due to bronchiolar constriction and abundant pulmonary secretions. There is urinary urgency and difficulty in voiding. The skin is ashen-gray in color and bathed in a cold perspiration. The heart rate is rapid, the pulse weak and the blood pressure at shock level. Consciousness is not disturbed except for faintness and the fear of impending disaster. A fatal outcome is usually caused either by pulmonary edema or central respiratory paralysis. Death may occur within one-half to two hours after symptoms are first noted.

Treatment consists of hypodermic or intravenous administration of one to two mgm of atropine sulfate, dependent upon the urgency of the case. Atropine quickly counteracts the serious effects of physostigmine, namely, those on the lungs and circulation, but it does not influence the annoying but innocuous skeletal muscle twitchings. These subside as the drug is eliminated from the body.

Absorption, Fate and Excretion. Physostigmine is readily absorbed from the gastro-intestinal tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures are not used (pressure on inner canthus) to prevent absorption from the nasal mucosa. The alkaloid is partly destroyed in the body and the remainder is rather rapidly eliminated through the kidneys. In man, a one mgm hypodermic dose of physostigmine has exercised its action and is practically completely eliminated in two hours.

Therapeutic Uses

The clinical uses of physostigmine are quite limited. Although the drug is sometimes employed in conjunction with acetylcholine or mecholyl to enhance and prolong their effects, it is ordinarily not so prescribed. The chief applications of physostigmine are for its ocular and intestinal actions, and for myasthenia gravis.

Uses in Ophthalmology. Physostigmine is used in *glaucoma* to reduce intraocular pressure. Although in very acute attacks solutions as strong as one to two per cent have been employed, it is considered safer by some to use much weaker solutions (0.02 per cent) for chronic medication. Lamellae containing the drug may also be employed. In alternation with atropine, physostigmine solutions (0.1 to 1.0 per cent) may be helpful in breaking adhesions between the iris and lens. The drug may be given after a mydriatic to bring the pupil back to normal size and lessen the danger of increased intraocular tension. It is also prescribed in treating marginal corneal ulcers, an empirical use not well understood. Watery solutions of physostigmine may be irritating and cause conjunctivitis. To avoid irritation, small amounts of cocaine may be incorporated in the solution or the free alkaloidal base may be administered in an oil.

Intestinal Uses. In conditions of gastro-intestinal atony, such as paralytic ileus following anesthesia and operations, or the distention accompanying certain acute infections or toxic processes, physostigmine may be employed to restore bowel activity and assist in the evacuation of gas. A hypodermic dose of one to two mgm may be given, or one mgm of physostigmine may be combined with one-half to one cc of solution of posterior pituitary. Prostigmine is preferred to physostigmine for use in intestinal ileus by some clinicians. Acetyl-beta-methylcholine is similarly employed.

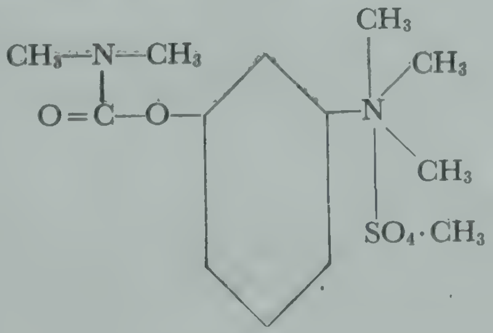
Martin and Weiss (1925) have suggested that much of the disappointment in the use of physostigmine in abdominal distention is due to two reasons—the administration of doses which are too small and the failure to distinguish between toxic and non-toxic cases. They find the average effective amount of physostigmine to be 3.0 to 4.0 mgm intramuscularly. This dose is safe if the patient is carefully observed, but should not be employed until simpler methods such as gastric or colonic irrigation, enemas and turpentine stupes have failed. Non-toxic cases (laparotomy, surgical shock, etc.) respond well but toxic cases (peritonitis, general toxemia, etc.) respond poorly or not at all.

Myasthenia Gravis. The use of physostigmine in myasthenia gravis is discussed under prostigmine.

PROSTIGMINE

Prostigmine is a synthetic alkaloid belonging to the physostigmine group of drugs. It is not to be confused with *geneserine,* an alkaloid found in the Calabar bean with physostigmine and sometimes referred to as prostigmine. Geneserine has the same qualitative actions as physostigmine but is only one-tenth as active (Heathcote, 1932). Prostigmine was introduced into therapeutics in 1931 for its stimulant action on the intestinal tract. Four years later it was found to be effective in the symptomatic therapy of myasthenia gravis.

Chemistry and Preparations. Prostigmine is available only in the form of its methylsulfate or bromide salt. The structural formula of prostigmine methylsulfate (dimethylcarbamic ester of 3-hydroxy-phenyl-trimethyl-ammonium methylsulfate) is as follows:



Prostigmine Methylsulfate

The salts are white crystalline powders which are odorless, bitter, and freely soluble and stable in aqueous solution. *Prostigmine Bromide,* N.N.R., being comparatively nonhygroscopic, is marketed in tablet form for oral administration. These tablets each contain 15 mgm of drug. *Prostigmine Methylsulfate,* N.N.R., is marketed in aqueous solution in 1.0 cc ampules containing either a 1:2000 (0.5 mgm) or 1:4000 (0.25 mgm) solution of the drug.

Relationship Between Chemical Structure and Action. Prostigmine is less complex in structure than is physostigmine. The researches of Stedman and collaborators (1926, *et seq.*) established the fact that the anticholinesterase activity of physostigmine and a number of allied compounds depended upon a fundamental chemical structure. Stedman's investigations established the fact that the methylcarbamic ester group, CH_3NHCOO, was the essential feature determining the activity of physostigmine and that all the related compounds manifesting anticholinesterase potency were basically substituted phenylesters of monoalkylcarbamic acids, having the general structure: $RNHCOOC_6H_4R^1$, R being a methyl or ethyl group and R^1 a basic group such as $—N(CH_3)_2$ or $—CH_2N(CH_3)_2$.

These important findings were extended by Aeschlimann and Reinert (1931) who studied a large series of synthetic compounds in an attempt further to elucidate the relationship between the structure and action of the physostigmine group and to find, if possible, drugs which might be more stable and more useful than physostigmine itself. One of the chemicals which these authors studied was prostigmine, which they found approximately as effective as physostigmine in producing miosis in cats and intestinal stimulation in rabbits.

Mechanism of Action. The mechanism of action of prostigmine, so far as is known at present, is similar to that of physostigmine—that is, it exerts its pharmacological effects by virtue of inhibiting the esterase which hydrolyzes and inactivates acetylcholine. No convincing evidence has yet been presented to prove that the highly selective actions of prostigmine are due to a *direct* effect of the drug on structures innervated by cholinergic nerves.

Pharmacological Actions. These need not be reviewed in detail because of their qualitative similarity to those of physostigmine. In man, prostigmine is said to be less active than physostigmine in causing miosis and spasm of accommodation. The same claim is made for its actions on the heart and blood pressure, but this important point needs confirmation.

On frog hearts at least, prostigmine has definitely weaker depressant actions than has physostigmine. In rabbits, doses of prostigmine necessary to lower the blood pressure are considerably larger than those which stimulate intestinal activity, but this also holds true for physostigmine. Prostigmine has the same effects as physostigmine on the intestine, urinary bladder and skeletal muscle, and is employed therapeutically for its actions on these structures. The drug further resembles physostigmine in possessing curariform effects on skeletal muscle when given in large doses. Therapeutic doses in man cause cutaneous vasodilatation, as indicated by a rise in temperature of the skin, but flushing does not occur (Perlow, 1939).

Atropine is the pharmacological antagonist to the muscarinic actions of prostigmine; curare, the antagonist to the skeletal muscle responses; nicotine, to the ganglionic actions.

Toxicology. The symptoms of prostigmine poisoning in man are similar to those seen with physostigmine (Goodman and Bruckner, 1937) and are described under the latter drug. The evidence available indicates that prostigmine has no wider margin of safety than has physostigmine. Indeed, the intravenous lethal dose of both drugs for mice is the same and toxicity studies in rabbits show that prostigmine given parenterally is from two to six times more lethal than physostigmine (Aeschlimann and Reinert, 1931). The use of prostigmine, therefore, demands the same caution and respect which attends the use of the older and more familiar drug physostigmine. In asthmatic patients, prostigmine may precipitate acute attacks of respiratory embarrassment and should therefore be employed with care.

Absorption, Fate and Excretion. Prostigmine is readily absorbed from the tissues after subcutaneous or intramuscular injection. It is also absorbed after oral administration, but much larger doses are needed by this route. Whereas the effective parenteral dose in man is from 0.5 to 2.0 mgm, the oral dose may be 30 mgm or more. Whether the drug is inactivated or destroyed in the intestinal tract or whether absorption is limited is not known. The large oral doses of prostigmine, such as are necessary in the therapy of myasthenia gravis, may prove toxic if intestinal absorption is enhanced for any reason. The exact fate of prostigmine in the organism is unknown. There is presumptive evidence that it is excreted in the urine.

Therapeutic Uses. Prostigmine is employed in therapeutics for its actions on the bowel, urinary bladder and skeletal muscle.

Intestinal Ileus. Prostigmine has been used in a manner similar to physostigmine for the relief of abdominal distention due to a variety of causes. The usual subcutaneous or intramuscular dose for postoperative intestinal ileus is 0.5 to 1.0 mgm of the methylsulfate salt. Peristaltic activity commences in from 10 to 30 minutes. A rectal tube should be inserted to facilitate the expulsion of gas. It may be necessary to assist evacuation with a small low enema.

The drug has also been employed in the prevention of postoperative intestinal atony, small doses (0.25 mgm) being given hypodermically soon after the operation and continued every four to six hours for two or three days. These small doses maintain normal intestinal tone without causing hyperperistalsis. The prophylactic administration of prostigmine is sometimes started before operation, but whether this is advisable as a routine procedure is doubtful. (*See* Harger and Wilkey, 1938; Marden and Williamson, 1939.)

Whether prostigmine is more valuable than physostigmine in paralytic ileus is a moot question. It is claimed by some that fewer side-actions (miosis, fall in blood pressure, bradycardia, bronchospasm, etc.) are noted after prostigmine.

Atony of the Urinary Bladder. Prostigmine has been employed for the prevention and treatment of atony of the detrusor muscle of the urinary bladder. The drug is used in the same dose and manner as in the management of intestinal ileus (Marden and Williamson, 1939).

Myasthenia Gravis. It was pointed out that myasthenia gravis may be due to a disturbance in the transmission of cholinergic nerve impulses to voluntary muscles, and the possible causes of the disorder were hypothecated (page 342). Regardless of the exact etiology of the disease, prostigmine and physostigmine, by inactivating cholinesterase, tend to increase the amount of acetylcholine at spinal motor nerve endings, and probably by this mechanism provide amelioration of symptoms.

In 1934, Dr. Mary Walker employed physostigmine in myasthenia gravis with beneficial results. She was prompted to do this because of the similarity of the muscular weakness in myasthenia to that noted in mild curare poisoning. In the following year, she found that better clinical results were obtained with prostigmine (Walker, 1935). Numerous clinical reports have confirmed these original findings. Why prostigmine is superior to physostigmine in myasthenia gravis is not known.

The exact mechanism by which prostigmine is of benefit in myasthenia gravis is not understood. Patients with this disease do not, as a rule, show abnormal values for *serum cholinesterase* (Lucas and coworkers, 1935; McGeorge, 1937; Hall and Lucas, 1937; Milhorat, 1938); but little is known concerning the cholinesterase activity of their skeletal muscles. It has been abundantly shown, however, that accompanying the improvement from the administration of prostigmine, there occurs a fall in serum cholinesterase activity. A similar fall occurs in the activity of skeletal muscle cholinesterase (Goodman, Carlson and Gilman, 1939). After the hypodermic administration of two or three mgm of prostigmine the serum cholinesterase activity is reduced from one-third to one-half of the resting level, with gradual restoration during a four to five hour period, toward the end of which the myasthenic symptoms return. The patient feels strong only during the period of drug-induced depression of the cholinesterase activity. The correlation between the improvement in symptomatology and the reduction in serum and muscle cholinesterase activity induced by prostigmine is illustrated in Figure 38.

The important relationship existing between potassium and cholinergic nerve transmission is discussed elsewhere (pages 341, 596) but it is interesting to observe at this point that Cumings (1939) has reported high values for potassium in the skeletal muscles of patients with myasthenia gravis. After the administration of prostigmine, the potassium content of the muscles decreased toward normal concurrently with the return of normal muscle power. The correlation of these findings with the anticholinesterasic property of prostigmine and with the cholinergic transmission of nerve impulses to skeletal muscles is not as yet clear.

Clinical Results. Striking improvement may appear in from 10 to 30 minutes after the parenteral injection of prostigmine, or within an hour or two after oral administration. The patient is benefited for from four to six hours and the drug is therefore repeated three or four times daily. Muscle power returns and a completely helpless individual can be transformed almost to normal. Ptosis, ophthalmoparesis, dyspnea, dysphagia, dysarthria and weakness of the neck, limbs and trunk are greatly or completely relieved. Patients can often return from invalidism to an ambulatory or even economically useful existence by the judicious use of prostigmine (Viets and Schwab, 1939).

In some patients, especially those who are severely ill, benefit may be temporary and can be sustained only by the use of larger and larger doses of the drug. These individuals require a progressively greater reduction in their (serum) esterase activity in order to maintain clinical improvement (Milhorat, 1938). The time may come when the drug is no longer capable of affording relief and a rapid downhill course then leads to death despite continued use of prostigmine. It is suggested that, if possible, other drugs (ephedrine, glycine, guanidine, choline esters) be substituted for prostigmine in such patients in an attempt to restore susceptibility to prostigmine. Some clinicians prefer to use prostigmine only as a supplement to ephedrine or glycine therapy. Others reserve it for use in emergencies. Nevertheless, the drug is an extremely valuable addition to the agents available in the therapy of myasthenia gravis. The combined use of ephedrine and prostigmine, in particular, comprises a valuable form of treatment, the two drugs apparently potentiating each other. The results obtained with prostigmine in combination with ephedrine, aminoacetic acid, guanidine, and certain other agents have been reviewed especially by Viets and Schwab (1939) and by Schlezinger (1940).

Dose. The initial hypodermic dose of prostigmine in myasthenia gravis is 0.5 mgm. This is then increased if necessary. The optimal dose is repeated two to four times daily. Because therapy is chronic, oral administration is much to be desired. This route is evidently safe, despite the large amounts of prostigmine

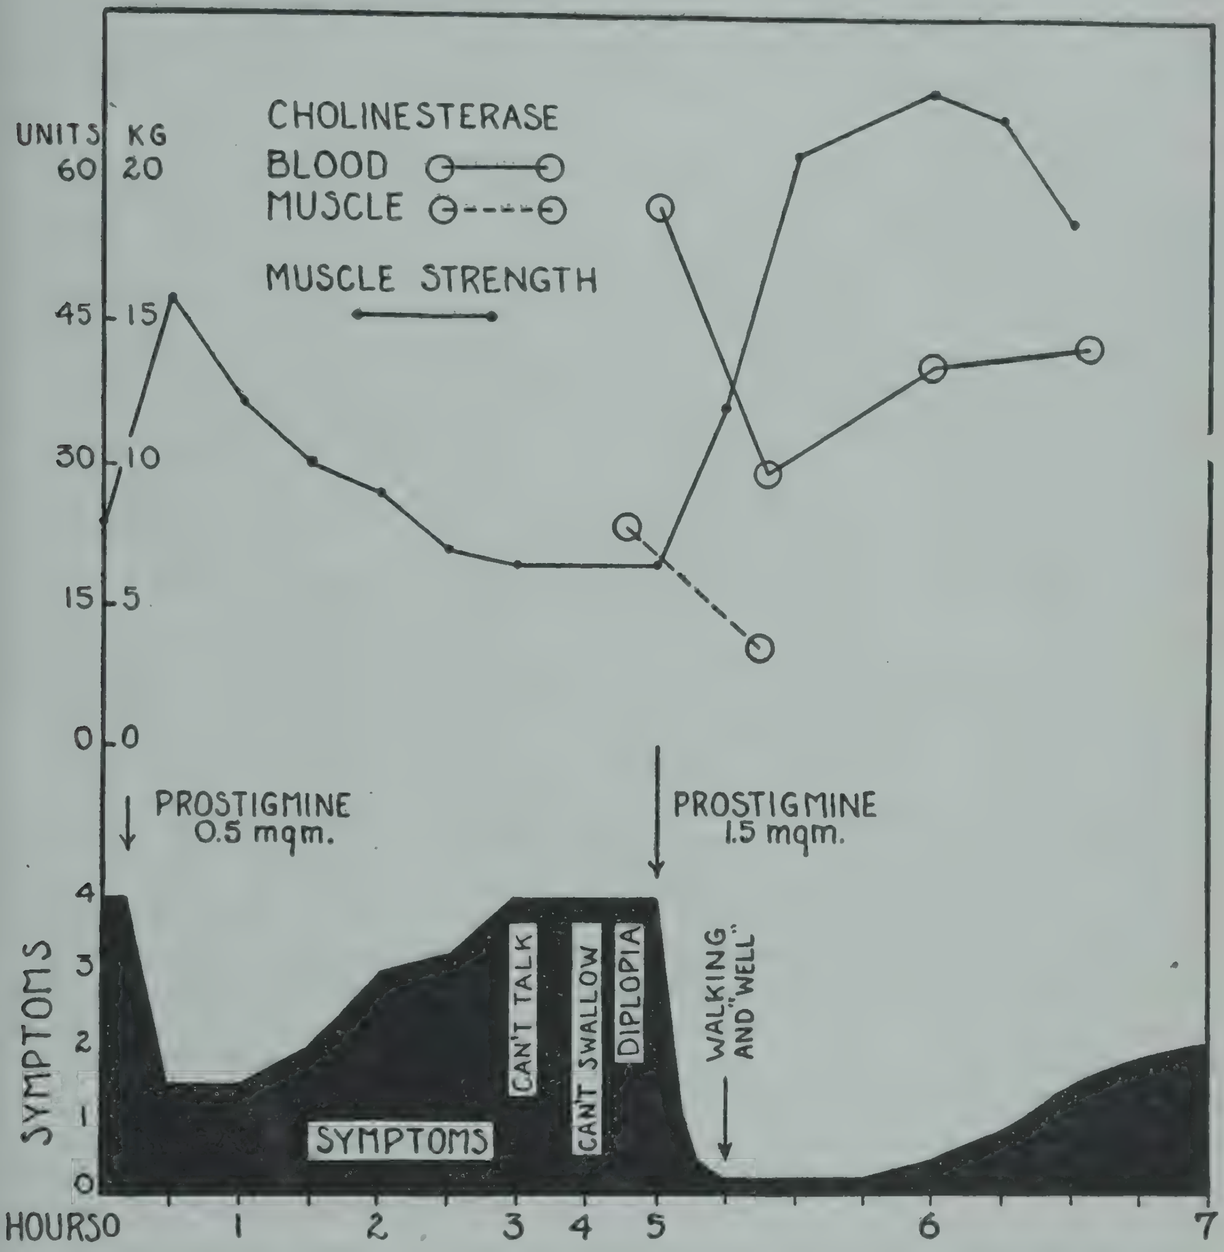


Figure 38. *The effect of prostigmine in myasthenia gravis.*

The severity of symptoms is shown on an arbitrary scale. Muscle strength was measured by a double hand-dynamometer. Pectoral muscle biopsies and blood samples were taken at the height of symptoms, and at the peak of improvement following the subcutaneous administration of prostigmine. One unit of cholinesterase is the amount which liberates 0.01 cc of 0.01 N acetic acid in five minutes from a solution containing 100 mgm of acetylcholine bromide in 25 cc.

The patient was a white male, aged 33, who had had myasthenia gravis for 16 years. Prostigmine in doses of 0.5 mgm caused only moderate relief of symptoms lasting less than two hours. Muscle strength decreased and symptoms progressed until the patient was absolutely helpless. After 1.5 mgm of prostigmine were injected, the patient was able to walk within 15 minutes, and said he felt "tops." Coincident with the symptomatic improvement there occurred a marked fall in the cholinesterase activity of the blood serum and muscle. Inhibition by prostigmine of the enzyme in skeletal muscle probably accounts for the increase in muscle strength. As symptoms returned, the cholinesterase activity of the blood increased. Note the change in time scale. (Goodman, Carlson and Gilman, 1939.)

necessary, provided atropine (0.3 mgm) or tincture of belladonna (0.6 to 1.5 cc) is used three times daily to prevent any of the untoward reactions on the intestinal, respiratory and cardiovascular systems. This prophylactic use of belladonna does not in the least impair the action of prostigmine on the skeletal muscles because atropine blocks only the muscarinic actions of parasympathomimetic drugs. The oral dose of prostigmine is from 15 to 30 mgm three times daily. Each patient must be studied carefully in order to find the optimal dosage, and frequent changes may be necessary in the dose schedule. Patients in relapse must be seen often.

Diagnostic Use of Prostigmine. Prostigmine has been tried in other myopathies characterized by muscular weakness, but the results have not been encouraging. These disorders include progressive muscular dystrophy, hypertrophic muscular dystrophy, amyotrophic lateral sclerosis, progressive ophthalmoplegia, progressive bulbar palsy, marked weakness following severe infections, etc. Indeed, so specific is the action of the drug in myasthenia gravis that prostigmine can be employed as a diagnostic test in doubtful cases (Viets and Schwab, 1935; Gammon and Scheie, 1937; Harvey and Whitehill, 1937), especially when used in conjunction with ergographic or electromyographic recordings. Quinine, which intensifies the symptoms of myasthenia gravis, may be given beforehand to those patients in whom symptoms are not well developed, and prostigmine may then be employed to improve the muscular weakness exaggerated by the quinine (page 908).

Other Drugs Useful in Myasthenia Gravis. In addition to prostigmine, several other pharmacotherapeutic agents are available for the symptomatic therapy of myasthenia gravis, including *ephedrine, benzedrine,* and the *choline esters* (*see* Index). *Glycine,* N.N.R., (glycocoll, aminoacetic acid), CH_2NH_2COOH, has also been observed to be of benefit in certain cases for varying periods of time (*see* Boothby, 1934; Report of the Council, 1935). It is a light, white, odorless, crystalline powder, possessing a sweetish taste and freely soluble in water. The dose varies from 15 to 30 grams per day, given in divided portions. The exact mechanism by which glycine exerts its effect on muscle contraction is not understood, despite the considerable information available from biochemical experimentation concerning the influence of aminoacetic acid on creatine-creatinine metabolism in health and in muscular dystrophies. *Guanidine,* $NH{:}C(NH_2)_2$, in the form of its *hydrochloride* or *carbonate* salt, has had a limited clinical trial in the treatment of myasthenia gravis. In some patients, it apparently is capable of causing symptomatic improvement alone or in combination with other drugs used in the syndrome, especially prostigmine (Minot, Dodd and Riven, 1939; Viets and Schwab, 1939). The initial dose is 10 mgm per kg taken orally in gelatin capsules, and the dose is increased as required. The total daily dose may vary from 10 to 35 mgm per kg, given in three or four divided portions. If necessary, the intravenous route may be employed, a two per cent solution of guanidine hydrochloride in isotonic sodium chloride being used. The subcutaneous and intramuscular routes cannot be utilized because of local irritation from the drug. The mechanism of action of guanidine in myasthenia gravis is unknown. Minot (1939) has shown that the chemical does not inhibit the activity of serum cholinesterase, and she and her coworkers (1939) are inclined to favor the view that guanidine increases the sensitivity of skeletal muscle to acetylcholine. The close chemical relationship between glycine, creatine and guanidine is evident, however, and suggests that glycine and guanidine may possibly exert their actions primarily by an effect on muscle metabolism. Patients with myasthenia gravis are evidently more tolerant of the chemical than are normal individuals who may experience symptoms of hyperguanidinemia, including nervousness, hyperperistalsis and diarrhea. *Potassium salts,* such as the *chloride* or *citrate,* have also produced improvement in the disease, and the rôle of potassium in the chemical mediation of nerve impulses may be the basis of the action of this cation in myasthenia gravis. Certain other muscular dystrophies, notably familial periodic paralysis, are also aided by potassium.

The aforementioned drugs may be employed in various combinations. Better results, for example, are often obtained when glycine and ephedrine or prostigmine and ephedrine are administered than when a single drug is used.

Other Uses. Prostigmine has had a preliminary but promising trial in *atrophic rhinitis.* Soskin and Bernheimer (1939) treated 14 patients suffering from advanced atrophic rhinitis with *ozena,* 0.25 cc of a 1:2000 solution of prostigmine methylsulfate being sprayed in each nostril four times daily. No untoward effects were noted. The degree of permanence of the beneficial results has not yet been established. Prostigmine has been shown to increase muscle tone in normal persons (McGeorge, 1937) and to cause a pronounced exacerbation of symptoms in *myotonia congenita* (Russell and Stedman, 1936; Kennedy and Wolf, 1937), a disease benefited by quinine. The drug has been employed in cases of *delayed menstruation* to induce the menstrual flow and as a *diagnostic test of early pregnancy.* Its value for these purposes requires confirmation. Prostigmine has also been administered orally for the treatment of *peripheral vascular disturbances* characterized by vasospasm or occlusive disease (Perlow, 1940). Prostigmine likewise has been used in a number of syndromes and diseases other than those mentioned but without definite benefit.

PHYSOSTIGMINE

CHAPTER 22

DRUGS STIMULATING STRUCTURES INNERVATED BY CHOLINERGIC NERVES (PARASYMPATHOMIMETIC DRUGS)

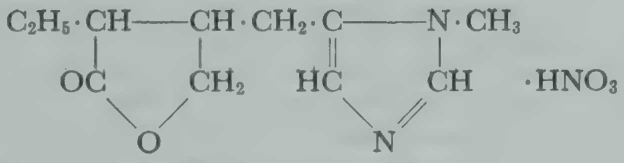
III. PILOCARPINE, ARECOLINE AND MUSCARINE

PILOCARPINE

Historical. Pilocarpine is the chief alkaloid obtained from the leaflets of South American shrubs known as *Pilocarpus jaborandi* and *Pilocarpus microphyllus.*

. The alkaloid was isolated by Hardy in 1871. Although it was long known by the natives that the chewing of leaves of *Pilocarpus* plants caused salivation, the first experiments were apparently performed in 1874 by a Brazilian physician named Coutinhou. Using an extract of pilocarpine, he showed that the drug also caused marked sweating. In 1876, the actions of pilocarpine on the pupil as well as on the sweat and salivary glands were described by Weber. Numerous other contributions to the pharmacology of this alkaloid rapidly followed.

Chemistry and Preparations. Pilocarpine base is a viscid, colorless oil which readily forms salts with mineral acids. Solutions of these salts are dextrorotatory. The hydrochloride and nitrate salts are available. *Pilocarpine Hydrochloride,* N.F., consists of very hygroscopic, colorless, translucent crystals. *Pilocarpine Nitrate,* U.S.P., B.P., consists of shining, colorless crystals, highly soluble in water and slightly bitter to the taste. The average adult oral dose of pilocarpine nitrate is five mgm. The structural formula of pilocarpine nitrate is as follows:



Pilocarpine Nitrate

Mechanism of Action. The autonomic responses to pilocarpine are due to a highly selective action of the alkaloid on cells innervated by postganglionic cholinergic fibers. This action is a direct one on the reactive substance and occurs after nerve section and complete nerve degeneration. Pilocarpine thus acts by an entirely different mechanism than does physostigmine. Pilocarpine is similar to muscarine and arecoline in its pharmacological properties and exhibits most of the muscarinic effects of acetylcholine. The nicotinic properties of acetylcholine are not manifest in the actions of pilocarpine. Atropine is the pharmacological antagonist to pilocarpine and counteracts or prevents all of the autonomic responses to the latter drug.

Pharmacological Properties

Pilocarpine stimulates the involuntary smooth muscle and gland cells innervated by postganglionic cholinergic nerves. Particularly responsive to pilocarpine are the sweat and salivary glands. The other actions of the alkaloid in the body, with the exception of miosis, are not therapeutically important and constitute undesirable side-effects. For this reason, pilocarpine lacks the wide range of usefulness enjoyed by the esters of choline. The alkaloid has few clinical uses and is perhaps not indispensable in medicine. It is unnecessary, therefore, to discuss in detail the responses of all autonomic structures to this drug.

Sweat Glands. For many years, the action of pilocarpine on sweat glands was viewed as an anomaly because the glands are devoid of parasympathetic innervation. It is now known that the nerve fibers supplying sweat glands, although anatomically sympathetic, are in reality cholinergic and this type of innervation explains their responses both to pilocarpine and atropine (page 331). Pilocarpine (10 to 15 mgm) causes marked diaphoresis in man when administered hypodermically and two to three liters of sweat may be secreted. This sweat contains not only the electrolytes of the extracellular fluid but also nitrogen in the form of urea. If the non-protein nitrogen of the blood is elevated, as in nephritis, the enhanced sweating caused by pilocarpine may allow for considerable extrarenal elimination of urea, amounting at times to as much as eight grams of nitrogen. Diaphoretic doses of pilocarpine, however, may also produce unpleasant side-actions such as hiccoughing, salivation, nausea, vomiting, weakness and occasionally collapse.

The *secretion of sweat* in man in response to pilocarpine and the esters of choline has been the subject of investigation by a number of workers, especially Wilson (1934) and List and Peet (1938). The diaphoretic response to these drugs is essentially similar, and has more pharmacological than clinical significance. The sweating produced by drugs is of limited diagnostic value in demonstrating the nature of peripheral nerve lesions, and it is much less pronounced in the lower extremities than in the rest of the body. It is claimed by some that the sweating reaction to drugs in man differs from that in animals, inasmuch as diaphoresis occurs in animals in cutaneous areas in which degeneration of nerves to sweat glands has taken place. This difference is denied by Wilson who found that after degeneration of the secretory ("sympathetic") nerves to sweat glands in human subjects, an excessive response occurred to pilocarpine (10 to 15 mgm) injected subcutaneously. In contrast, sensory nerve degeneration was usually associated with a diminished secretory response to pilocarpine, probably due to alterations in the cutaneous vascular bed. Wilson also demonstrated that intradermal injection of solutions of pilocarpine caused a "triple response," similar to that caused by histamine (page 561), and local sweating. Atropine injected into the same area caused prompt cessation of the sweating. Wilson concluded that pilocarpine acts directly on sweat glands in man and also that it dilates the minute vessels of the skin. Similar results were obtained with acetylcholine. The intervention of secretory nerve endings evidently is not essential for the sweating response to these drugs.

List and Peet likewise investigated the sweating response in man to subcutaneously administered pilocarpine (10 to 16 mgm) and acetyl-β-methylcholine (12 to 25 mgm). They found that thermoregulatory sweating disappears completely after various forms of sympathectomy in which the postganglionic cholinergic fibers to the glands are interrupted, and that the heat test of sweating is a simple and accurate clinical method to determine the extent and site of lesions in the sympathetic nervous system. Pilocarpine and mecholyl still induce sweating after sympathectomy, but no longer do so after degeneration of mixed peripheral nerves or purely sensory cutaneous nerves. Heat sweating also disappears after section and degeneration of peripheral cutaneous nerves. When the somatic nerve is blocked by infiltration with procaine, however, only heat and not drug-induced sweating disappears.

The presence in peripheral somatic nerves of cholinergic fibers to sweat glands other than those of sympathetic origin appears likely; but it is not at all clear why complete anhidrosis should follow interruption of these nerves by resection and not after infiltration with procaine. List and Peet are inclined to interpret their findings as indicating a direct action of pilocarpine and mecholyl on nerve endings rather than on sweat glands. Such a conclusion is certainly not in harmony with the bulk of evidence concerning the action of drugs on autonomically innervated structures. Present concepts hold that autonomic drugs act directly on effector cells and not on nerve endings (page 336), act regardless of the integrity of the innervation, and indeed may show enhanced potency after complete denervation of the effector organs (page 342). In this connection, an additional observation of Wilson is pertinent. The sweating which followed the intracutaneous injection of acetylcholine could be prolonged by the prior local injection of eserine, which prevented the hydrolytic destruction of acetylcholine by cholinesterase in the skin. No such potentiation by eserine of the sweating response to intradermally administered pilocarpine was demonstrable, thus indicating that pilocarpine did not stimulate nerve endings to release acetylcholine. The anomalous behavior of drug-induced sweating responses in man with various types of peripheral nerve injury or section awaits further elucidation.

Other Glands. Many glands which receive postganglionic cholinergic fibers and elaborate external secretions are stimulated in varying degrees by pilocarpine. These include the salivary, lacrimal, gastric, pancreatic and intestinal glands, and the mucous cells of the respiratory tract. Copius *salivation* follows the administration of therapeutic amounts of pilocarpine. In man, as much as 350 cc may be secreted over a period of two hours in response to 10 mgm of the drug. Normal saliva is one of the few hypotonic fluids that the body elaborates and is also unique in containing a larger amount of potassium than does the extracellular fluid from which it is derived. After pilocarpine, the saliva tends to approach in composition that of an ultrafiltrate of the serum.

The *gastric glands* are stimulated to secrete a juice rich in acid but especially abundant in pepsin and mucin, simulating in this respect the effects of vagal impulses. Only certain choline esters exceed pilocarpine in this ability to stimulate the secretion of pepsin. Pilocarpine is inferior to histamine in causing secretion of hydrochloric acid. The effects of pilocarpine on *pancreatic* and *intestinal* secretions are not prominent. The glands of the *respiratory* tract are activated by the alkaloid, large doses of which can produce sufficient bronchiolar secretion to cause pulmonary edema.

Eye. Pilocarpine nitrate, when applied locally to the eye, causes pupillary constriction, spasm of accommodation and a transitory rise in intraocular pressure, followed by a more persistent fall. Miosis lasts from several hours to a day, but fixation of the lens for near vision disappears in about two hours.

Other Actions. Theoretically, all structures receiving cholinergic innervation are stimulated by pilocarpine but this generalization does not hold true for the heart. Slowing of the heart is fleeting and uncertain. Cardiac rate may actually be increased in man by therapeutic doses of the drug (Wilson, 1934). Peripheral vasodilatation occurs after pilocarpine, but is less marked than the response to acetylcholine and muscarine. The *blood pressure* therefore does not fall, and in fact it may rise somewhat, especially the systolic level (Blomberg and Rönnell, 1930; Wilson, 1934). These apparently anomalous reactions of the cardiovascular system to pilocarpine are not well understood.

The alkaloid stimulates the *smooth muscles* of the *intestinal tract*, thus increasing tone and motility, and large doses cause marked spasm and tenesmus.

The tone and motility of the *ureters, urinary bladder, gall bladder* and *biliary ducts* are also enhanced by pilocarpine. The *bronchioles* are constricted by pilocarpine and this action, in conjunction with the enhanced secretory activity of bronchial glands, results in a condition simulating bronchial asthma. The *spleen* contracts due to stimulation of its capsular musculature. This is probably the basis for the *leukocytosis* sometimes noted after the drug.

When injected into the *cerebral ventricles* of man, small doses of pilocarpine (2.5 mgm) cause widespread vasodilatation, sweating, vomiting and decrease in body temperature (Cushing, 1932). Similar effects have been noted from intraventricular instillation of posterior pituitary substance, and the phenomenon has been interpreted as a central autonomic stimulation, predominantly parasympathetic in character. These central responses are not noted after oral or hypodermic administration of pilocarpine. Other actions of the alkaloid on the nervous system are not prominent, but large doses cause central depression.

Pilocarpine Poisoning. Poisoning due to pilocarpine is rare. The symptoms simulate those of muscarine to which the drug is pharmacologically closely allied. Marked salivation, lacrimation and sweating occur. Nausea, vomiting, tenesmus and diarrhea are prominent. Vision for far objects is blurred and the pupils are greatly constricted. Breathing may be difficult due to bronchiolar spasm, and edema of the lungs from excessive secretion may prove fatal. The pulse rate may be fast or slow and the blood pressure falls. Muscular weakness, tremor, vertigo, confusion, marked depression and ultimately collapse ensue. Death is usually due either to pulmonary edema or central respiratory failure, and may occur within a few hours. The *fatal dose* is unknown but 100 mgm may be viewed as a dangerous amount. *Treatment* consists of administration of atropine, and symptomatic measures designed to support the respiration and circulation and to counteract edema of the lungs.

Fate and Excretion. Pilocarpine is partly destroyed in the body but the greater part is excreted in the urine in combined form.

Therapeutic Uses. *Eye.* Pilocarpine is used to produce miosis. It can be administered as a 0.5 to 3.0 per cent solution, in the form of an ointment or in gelatin lamellae. The miotic action of pilocarpine may be useful in overcoming the mydriasis of atropine, or in glaucomatous conditions. Alternated with mydriatics, pilocarpine may be employed to break adhesions between the iris and the lens.

Diaphoresis. The practice of using pilocarpine to cause sweating in order to rid the body of edema fluid, exudates or nitrogenous material is now practically obsolete. Severe side-effects accompany the use of effective diaphoretic doses. If sweating or fluid elimination is desired, safer and less strenuous methods are available. Pilocarpine, as was stated previously, has been employed in investigating disturbances in the sweating mechanism as a result of peripheral nerve lesions, the moisture being detected either by the red color imparted to an alcoholic solution of cobalt blue previously painted on the skin or by the iodine color reaction test of Minor (1927). Small doses of the alkaloid have been used to alleviate generalized *itching,* as in portal cirrhosis. The mechanism of relief may be related to sweating or to slight changes in the cutaneous circulation.

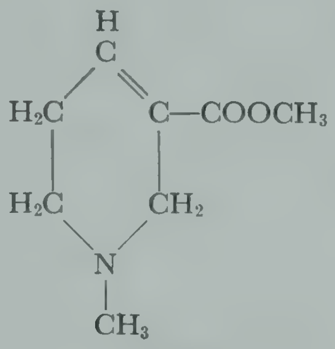
Salivation. Pilocarpine may be given to induce salivation when xerostomia is an unpleasant symptom, as in atropine overdosage or botulism.

Miscellaneous Uses. Pilocarpine is occasionally incorporated in medicines for use in unproductive coughs, where it may act as an *expectorant* by virtue of its stimulation of bronchial glands. The drug has gained a false reputation as a hair restorer, based on its action on sebaceous glands, and it is thus incorporated in certain hair tonic nostrums. No beneficial effect can reasonably be expected after local cutaneous application of the alkaloid. Pilocarpine is useful to a certain degree in counteracting the peripheral autonomic effects in cases of *atropine poisoning,* but the serious features of the intoxication, which are due to the central actions of atropine, are unaffected.

ARECOLINE

Arecoline is the chief alkaloid of areca nuts, the seeds of *Areca catechu.* This nut is also known as the *betel nut* because it has been consumed by the natives of the East Indies from early times in a masticatory mixture known as *betel* and composed of the areca nut, shell lime and the leaves of *Piper betle,* a climbing species of pepper. The mixture stains the teeth black. The use of betel nut as a taenicide was known to the Chinese as early as the 6th century, and the nut is still employed for that purpose in China (Hsiao-Liang, 1936).

Chemistry and Preparations. Arecoline is a reduced pyridine derivative with the following relatively simple structure:



Arecoline

There is no apparent chemical basis for the similarity in actions of arecoline, pilocarpine and muscarine. *Areca* (Areca Nut, Betel Nut), N.F., is the dried ripe seed of the plant. The N.F. alkaloidal salt is *Arecoline Hydrobromide,* a white, crystalline, water-soluble powder.

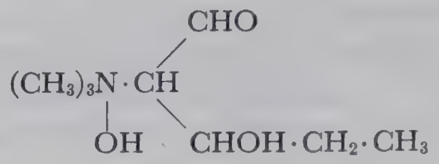
Actions. Arecoline shares many of the pharmacological properties of pilocarpine and muscarine in that it stimulates, by a direct action, those smooth muscles and gland cells innervated by postganglionic cholinergic nerve fibers. It is qualitatively similar in action to pilocarpine in all respects but is more powerful.

Uses. Although arecoline is official in certain pharmacopeias and is employed as a diaphoretic, sialogogue and taenicide in some parts of the world, it is not prescribed in modern therapeutics. Arecoline is occasionally utilized in veterinary medicine as a vermifuge, the expulsion of worms being accomplished by the marked stimulation of peristalsis which the drug produces. The average dose for a horse is 30 mgm; for a dog, 1.5 mgm per kg. The use of betel nut as a taenicide by the Chinese has been mentioned. The charcoal obtained from areca is very hard and is sometimes incorporated in dentifrices.

MUSCARINE

Muscarine is a drug which, though not employed clinically, is of considerable historical and experimental significance. The poisonous effects of certain species of mushrooms were known for a long time but it was not until Schmiedeberg isolated the alkaloid muscarine from *Amanita muscaria* that the properties of the drug could be systematically investigated. Schmiedeberg and Koppe made the first careful pharmacological study of muscarine in 1869. The close resemblance between the responses to vagal stimulation and to muscarine led Dixon to postulate that a muscarine-like substance might be the chemical agent through which vagal impulses were mediated (page 324).

Chemistry. Muscarine is a quaternary ammonium base with the following structural formula (Kögl and associates, 1931):



Muscarine

Its close chemical relation to choline, another constituent of *Amanita muscaria*, and to the esters of choline can be seen by comparison with the formulas shown on page 351.

Actions. Muscarine, by a direct action, stimulates smooth muscles and gland cells innervated by postganglionic cholinergic nerves. Thus it shares the pharmacological properties of pilocarpine and arecoline, and particularly those of acetylcholine, because, like the last-named drug, it causes typical cardiac slowing and peripheral vasodilatation. So similar are the responses of the heart, smooth muscles and glands to muscarine and acetylcholine that the term "muscarinic" is employed to designate the action of acetylcholine on these structures, in distinction to the "nicotinic" action of acetylcholine on autonomic ganglia and skeletal muscles (page 339). Muscarine, however, can be shown to possess some nicotinic properties but these are not prominent. As might be predicted, the chief effects of muscarine in the mammalian organism are cardiac slowing, depression of blood pressure, vasodilatation, increased peristalsis, miosis, bronchial constriction, salivation and sweating. Small doses of atropine completely inhibit these responses to muscarine.

Uses. Muscarine has no therapeutic uses, and is mainly of laboratory interest as a pharmacological tool. It is rather difficult to obtain in pure form.

Mushroom Poisoning (Mycetismus)

Mushroom poisoning has been known for centuries. The Greek poet Euripides (5th century B.C.) is said to have lost his wife and three children from this cause. Mushrooms were employed by professional poisoners in ancient times. The increased incidence of mycetismus during the early 1930's has been attributed to the eating of wild mushrooms because of the economic depression.

The *Amanita* genus of mushroom is responsible for nearly all cases of mushroom poisoning in the United States, and the delicious but deadly *phalloides* species causes over 90 per cent of the fatalities. Occasionally, *Amanita muscaria* may cause death. These two species are common in North America. Poisonous mushrooms can be differentiated from edible ones only by their botanical characteristics and not by such fallacious lay tests as the tarnishing of silver coins placed in the cooking utensil. Rarely does the physician have an opportunity to identify the type of plant responsible for the intoxication and he must therefore depend on the history and symptoms in order to make his diagnosis. Two types of mushroom poisoning occur in the United States, the *rapid* and the *delayed*.

The *rapid* type (mycetismus nervosus) is caused by *Amanita muscaria* which contains the alkaloid muscarine. Symptoms are due especially to muscarine and occur within a few minutes to an hour or two after ingestion of the fungus. They are similar to those described under pilocarpine poisoning. There is marked lacrimation, salivation, sweating, miosis, dyspnea, severe abdominal pain, frequent watery and painful bowel evacuations, cardiovascular collapse, vertigo, weakness, confusion, coma and occasionally convulsions. In fatal cases, death occurs within a few hours. Atropine provides a specific antidote and the prognosis is good even in severe cases if this form of intoxication is recognized and atropine is administered.

The *delayed* form (mycetismus choleriformis) is due to *Amanita phalloides* which probably contains several toxins, as yet not completely identified. Symptoms occur in from six to 15 hours after ingestion of the fungus and are heralded by the sudden onset of severe abdominal pains, nausea, vomiting and diarrhea. The stools and vomitus are often blood-streaked. Dehydration is marked and thirst is extreme. The course of intoxication is prolonged. Jaundice develops in two or three days secondary to severe degenerative changes and fatty infiltration of the liver. Acute yellow atrophy of the liver may also occur. The kidney parenchyma is similarly involved and oliguria or anuria ensues. Cyanosis, low blood pressure and feeble heart action are the result of extensive capillary damage and a direct toxic action on cardiac muscle. Increasing prostration terminates in coma, which is probably due in large part to the direct cellular damage in the central nervous system produced by the *Amanita phalloides* toxin. The prognosis is grave. The mortality rate is at least 50 per cent, and often approaches 100 per cent. Death occurs in from five to eight days after the ingestion of the mushrooms. Treatment is purely symptomatic and supportive, and includes prolonged rest in bed, opiates for pain, and shock therapy when indicated. The value of antitoxic sera in cases of poisoning by *Amanita phalloides* is unproved.

The interested reader is referred for the classification and details of mushroom poisoning especially to Ford (1923) and Vander Veer and Farley (1935). The botanical characteristics of these fungi, which are not germane to the present discussion, may be found in botanical and pharmacognosy texts.

CHAPTER 23

DRUGS STIMULATING STRUCTURES INNERVATED BY ADRENERGIC NERVES

(SYMPATHOMIMETIC DRUGS)

I. EPINEPHRINE

A large number of sympathomimetic drugs are known and several of these are widely used in therapeutics. Although they resemble each other in many respects, each possesses certain unique properties which are often of value for specific clinical purposes. In general, the sympathomimetic amines elicit responses in the body which simulate those resulting from stimulation of adrenergic nerves, but the details and intensities of these responses often differ widely. In addition, several of the compounds produce profound effects on the central nervous system. Drugs in this category thus have a variety of clinical uses and it is therefore necessary for the physician not only to understand the general pharmacology of the group as a whole but also the manner in which the various members differ. In the following discussion, particular attention will be paid to the two older members of the group, epinephrine and ephedrine, and the many similarities and differences between these two compounds will serve as a background for the description of the agents which have subsequently been introduced.

EPINEPHRINE

Source and History. Epinephrine, the active principle of the adrenal medulla, was the first hormone to be isolated in crystalline form. Curiously, epinephrine is also found, along with substances resembling cardiac glycosides, in the secretions of glands of toads, and the parotid glands of a single Jamaican toad (*Bufo marinus*) contains more than four times the amount of hormone present in a pair of human suprarenal glands. Epinephrine is closely related to the amino acid *tyrosine* which may be the precursor of the hormone in the animal body. Decarboxylation of tyrosine yields *tyramine,* a substance found in ergot and putrefying meat and formed from protein in the intestinal tract in the presence of bacteria. Tyramine resembles epinephrine in its sympathomimetic properties but is much weaker. The *in vitro* synthesis of an epinephrine-like substance from phenylethylamine, phenylalanine and tyramine, but not from tyrosine or methyl tyrosine has been demonstrated by Devine (1940) to occur in surviving tissue slices of the adrenal medulla (bullock).

In 1895, Oliver and Schäfer demonstrated the actions of extracts of the adrenal medulla on the cardiovascular system, marked rises in blood pressure occurring after intravenous injection of the extracts into animals. No such potent vasopressor substance was known at that time, and their experiments initiated intensive pharmacological investigations which soon resulted in the elucidation of the chemical structure of the active principle through the efforts of Abel (1897, 1899), von Fürth (1900), Takamine (1901), Aldrich (1905) and others. Epinephrine was then synthesized independently by Stolz (1904) and Dakin (1905), and its optical isomers separately by Flächer (1908). The history of the isolation and identification of epinephrine has been reviewed by Hartung (1931).

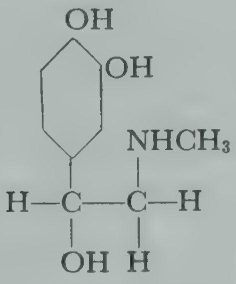
Barger and Dale (1910) examined a large series of related synthetic amines, defined the basic structural requirements for pharmacological activity and introduced the term "sympathomimetic" to describe the type of action manifested by the group as a whole. The details of their now classical contribution are included in the discussion of the relationship between chemical structure and pharmacological properties.

In the early 1920's, the investigations of Loewi and Cannon and their respective collaborators disclosed the importance of an epinephrine-like substance in the mediation of the excitatory state produced by nerve impulses at neuromuscular and neuroglandular junctions. The significance and details of these discoveries and the concept of sympathin E and sympathin I are presented in detail in Chapter 19.

Chemistry of Epinephrine and Related Compounds and the Relation of Chemical Structure to Pharmacological Activity. Shortly after the chemical structure of epinephrine was determined, studies of the pharmacological actions of chemically related compounds began to appear. Investigations of this nature have continued to the present and have resulted in the introduction of many valuable therapeutic agents.

The first extensive study on compounds chemically related to epinephrine was the classical investigation of Barger and Dale (1910). The conclusions drawn by them are still valid and their work formed the impetus not only for the study of compounds chemically related to epinephrine but stimulated interest in synthetic drugs in general. Some of the compounds which Barger and Dale investigated are only now becoming prominent. For these reasons a brief summary of their experiments is not only of historical but also of current interest.

Before considering the contributions of Barger and Dale, a study of the chemical structure of epinephrine is pertinent. Its structural formula is as follows:



Epinephrine

The epinephrine molecule may be viewed as composed of two major constituents. The aromatic portion consists of dihydroxybenzene (catechol); the aliphatic, of alpha-hydroxy-beta-methylamino ethane. In the following discussion, the carbon atom attached to the benzene ring is designated as the *alpha* carbon.

Barger and Dale began their study with an investigation of simple aliphatic amines. They observed that amines of low molecular weight (I) had no sympathomimetic activity (Roman numerals refer to compounds listed in Table 20). When a four carbon atom structure was reached (II), however, definite activity appeared, reached its maximum with six carbon atoms (III) and then receded as the length of the aliphatic chain was further increased (IV). In the aliphatic series, substitution in the amino group resulted in a loss of activity and quaternary ammonium bases possessed an entirely different type of action which resembled that of curare. They then went on to study the effect of introducing a phenyl group into simple aliphatic amines. The presence of the aromatic ring increased activity and of this series phenylethylamine (V) was the most potent. Decreasing or increasing the number of carbon atoms on the aliphatic portion of the molecule resulted in a loss of activity. Furthermore, the presence of a hydroxy group on the alpha carbon (VI), or a methyl group on the nitrogen, or both (VII), failed to increase activity. Barger and Dale then studied the effect of adding one hydroxy group to the benzene ring. If the hydroxy group was placed para (VIII) or meta (IX) to the aliphatic chain, activity was increased three to five times, but ortho substitution (X) was without effect. As before, two carbon atoms before the nitrogen gave maximal activity. Also, as before, the presence of a hydroxy group on the alpha carbon atom (XI) or a methyl group on the nitrogen (XII) failed to affect pharmacological actions.

Table 20

Dihydroxyphenyl Amines	 XIII	 XIV	 XV		

* See text for explanation.

Barger and Dale then proceeded to a consideration of compounds possessing two hydroxy groups in the benzene ring. Only when the hydroxy groups were in the para and meta positions (XIII) was activity enhanced. In this series, however, the insertion of a methyl group into the primary amine (XIV) further increased activity five to 10 times. Ethyl amines and propyl amines were less active than methyl amines. Nevertheless, even the methylamine derivative was only 1/7 to 1/10 as active as epinephrine. On the other hand, if instead of substituting in the amino group, a hydroxy group was placed on the alpha carbon atom (XV), a greater increase in activity was noted. Compound XV possesses an asymmetrical carbon atom. The synthetic d-l form, when compared with d-l epinephrine, was found to be even slightly more active.

In the course of their investigations Barger and Dale noted that the excitatory and inhibitory effects of epinephrine derivatives did not increase and decrease in a parallel manner. Neither did they note a relationship between stability and activity. Their most basic conclusion was that sympathomimetic activity in the aromatic compounds depends upon a benzene nucleus separated from an amino nitrogen by two carbon atoms. All the sympathomimetic compounds of therapeutic value which are at present available possess this basic structure, and many represent substances which were originally investigated and prepared by Barger and Dale (compare Tables 20 and 21).

The next significant advance, which was to lead to the preparation of many new and valuable sympathomimetic drugs, was the elucidation of the structure of ephedrine. Ephedrine was found to possess many of the basic chemical features of the series of compounds studied by Barger and Dale. Thus it contains a benzene nucleus separated from an amino nitrogen by two carbon atoms. On the alpha carbon of the aliphatic chain is a hydroxy group, and on the nitrogen of the amine, a methyl group. Ephedrine, however, differs radically in that it contains one more carbon atom on the aliphatic chain. As a result, pharmacologists synthesized and investigated another series of compounds, related to those originally studied by Barger and Dale but differing in possessing three carbon atoms in the aliphatic portion of the molecule. The position of the benzene group relative to the nitrogen was retained. Outstanding sympathomimetic drugs possessing unique therapeutic applications have resulted.

The chemical relationships of all the available sympathomimetic drugs of therapeutic importance can easily be appreciated if one regards their structure in the light of the foregoing discussion. In brief, in the compounds of this series there are two important portions of the molecule, the aromatic and the aliphatic. The aromatic portion is benzene; monohydroxybenzene or dihydroxybenzene. The aliphatic portion consists of a two or three carbon atom chain. In every instance the second or beta carbon atom has an amino group attached. There may or may not be a methyl group attached to the amino nitrogen. There may or may not be a hydroxy group on the alpha carbon atom. If there is a third carbon atom, it always consists of an unsubstituted methyl group. These variables permit many variations in structure and this accounts for the large and increasing number of sympathomimetic agents. The chemical structures and interrelations of the more important of these are presented in Table 21.

Although one can predict with remarkable accuracy from its chemical structure whether or not a compound possesses sympathomimetic activity, further relationships between structure and action are difficult to define. Various organs respond in a somewhat different manner and to a different degree to individual sympathomimetic agents. In addition, some of the compounds have marked effects on the central nervous system. Also the drugs vary in their stability. Those agents possessing a three carbon atom aliphatic chain are more resistant to destruction than those with a two carbon atom chain, and the dihydroxybenzene derivatives have the least stability. Few compounds approach epinephrine in pressor activity, but several partake of new properties which greatly increase their field of usefulness.

The derivatives of epinephrine which are employed in therapeutics represent only a small proportion of the more than 200 compounds which have been synthesized and studied. A mere attempt to point out the possible relationships between chemical structure and pharmacological action of the relatively few compounds presented in Table 21 would be beyond the scope of the present discussion. Numerous efforts have been made to correlate the various aspects of this field and such studies may eventually lead to a more basic understanding of the mechanism of action of the drugs of the epinephrine group (*see* Chen and coworkers, 1929; Hartung, 1931; Tainter, 1933, *et seq.;* Patek and Thienes, and coworkers, 1934, *et seq.;* Crimson and Tainter, 1938; Tainter and coworkers, 1939; Youmans and coworkers, 1939; Jacobsen and coworkers, 1938, 1939; Gunn, 1939; Drake, Renshaw and Thienes, 1939; and others). Of greater importance from the point of view of the application of these compounds in therapeutics is a description of the individual drugs and their pharmacological characteristics.

Mechanism of Action. Insofar as it is now understood, epinephrine acts directly on effector cells. This is clearly shown by the response of denervated organs to epinephrine (page 343), and also by the finding of Euler (1938) that the drug constricts the perfused vessels of the human placenta, which are thought to

be devoid of nerve supply. Whether epinephrine affects the receptor substance or the contractile or secretory elements of cells is not known. Certain structures in the body are stimulated by epinephrine; others are inhibited. For example, some smooth muscles are contracted, others relaxed by the drug; but whether there is a substance in the cell which determines the augmentative or inhibitory nature of the response has not been determined (page 337). Denervation of effector organs receiving adrenergic nerves greatly enhances their sensitivity to epinephrine and this fact is of considerable clinical importance in patients with postganglionic sympathetic neurectomies. The duration of action of epinephrine in the body is determined by its rate of destruction, the drug being oxidized fairly rapidly. Epinephrine and sympathin are more stable than acetylcholine in the body, and the importance of this fact in the functional organization of the autonomic nervous system has already been pointed out. A highly specific enzyme in the tissues such as that destroying acetylcholine (cholinesterase) does not exist for epinephrine. The influence of cocaine on the responses to epinephrine is discussed elsewhere as well as the effects of the *ergot* alkaloids and the relationship between *potassium* and the actions of epinephrine. Further details of the mechanism of action of epinephrine and its physiological rôle in maintaining the internal economy of the body are presented in Chapter 19.

Pharmacological Actions

In general, the actions exhibited in the body by epinephrine resemble those obtained from stimulation of adrenergic nerves. Thus, most of the responses listed in Table 17 are observed after injection of the drug in man. Sweating and pilomotor reactions, however, are not elicited, and mydriasis is not obtained except under special circumstances. Particularly prominent are the actions of the drug on the heart, blood vessels and certain smooth muscles, and these actions provide the basis for the chief therapeutic uses of the drug. So enormous is the pharmacological and physiological literature on almost every aspect of the numerous changes induced by epinephrine in bodily functions that it is only by means of a judicious restriction in the number of citations of original experiments that one can hope to present the subject within the scope of this text. For this reason also, data pertaining to the actions of the drug in man receive precedence over the more abundant results from animal experimentation.

Cardiovascular Actions. Epinephrine has numerous and complex effects upon the cardiovascular system. One of the most dramatic sights in all pharmacodynamics is the blood pressure response elicited in animals by the intravenous injection of minute amounts of the drug (Figure 39), and it is this action which so impressed Oliver and Schäfer in their original study of adrenal extracts. The heart rate is accelerated, the myocardium stimulated, the cardiac output enhanced, the cardiac rhythm often altered and the blood vessels are constricted in some areas and dilated in others. In addition, the responses are modified by the compensatory reflexes which are evoked through the carotico-aortic presso-receptor system in an attempt to return the cardiovascular status to normal. This involves increased activity of the vagal and vasodilator mechanisms. Also, inasmuch as epinephrine is thought to embody the properties of both sympathin E and sympathin I, the size of the dose administered may determine whether vasodilatation takes precedence over vasoconstriction. Finally, the presence of disease, anesthesia, and other factors modify the responses obtained. It is little wonder, then, that experimental data on the actions of the drug are sometimes conflicting.

Blood Pressure. Epinephrine is the most potent vasopressor drug known. When it is given intravenously to animals, a characteristic type of blood pressure response is evoked. Both the systolic and diastolic blood pressures rise rapidly to a peak which is proportional to the dose administered, and then quickly fall to normal. At the height of the rise, the pulse rate, accelerated at first, may be slowed markedly due to compensatory vagal discharge. This bradycardia is blocked by atropine or section of the vagi.

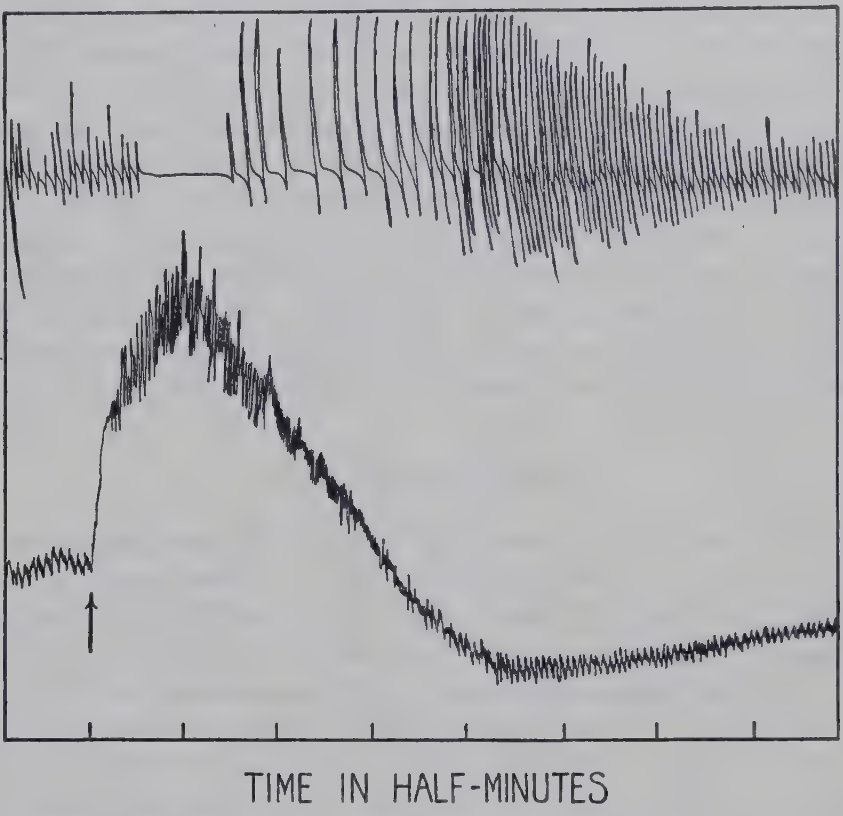

Figure 39. *The effect of intravenous epinephrine on the blood pressure and respiration.*

Dog, weight 7 kg, amytal anesthesia, vagi intact. Upper tracing, respiratory movements; lower tracing, blood pressure; time in half-minute intervals. At the arrow, 0.05 cc of a 1:1000 solution of epinephrine hydrochloride was injected intravenously. Observe the sharp rise in blood pressure, the bradycardia and increased pulse pressure at the height of the rise ("vagal effect"), the subnormal phase which appears after the pressor effect has subsided, and the evanescent character of the response to epinephrine. Note also the cessation of respiration ("epinephrine apnea") which occurs at the height of the pressor effect. (After Abel and Geiling, 1928. Courtesy of the Chemical Foundation, Inc.)

When the blood pressure has returned to normal, successive administrations of the same dose of epinephrine produce equipressor responses, in sharp contrast to the effect of repeated doses of ephedrine. The height of the rise in blood pressure is so closely proportional to the amount of epinephrine injected that the pressor response in dogs can be used for the assay of the drug. The cause of the rise in blood pressure produced by epinephrine is three-fold—direct myocardial stimulation, increased heart rate and peripheral vasoconstriction of the finer arterioles, the caliber of which controls in large measure the level of the diastolic blood pressure.

After the pressor response to epinephrine has subsided, the blood pressure does not return directly to normal, but rather there is a short period of *hypotension.* This phase of action of epinephrine is of clinical as well as academic importance. Various explanations have been offered to account for the *diphasic* action of the drug on the circulation. One is that epinephrine causes dilatation of the capillaries, an effect which is at first overshadowed by the marked arteriolar constriction. When the latter action has worn off, the more persistent capillary dilatation exhibits itself and consequently the blood pressure is reduced below normal. A more likely explanation, however, and one for which considerable collateral evidence exists, is that epinephrine combines the properties of sympathin E and sympathin I. The former constricts and the latter relaxes blood vessels. The vasodilator component of epinephrine is weaker but has a more prolonged duration of action than the vasoconstrictor component. Thus its effects are at first masked by marked arteriolar contraction, but when the excitatory action has worn off, the inhibitory factor is still present to cause vasodilatation. Under certain circumstances, the inhibitory component is predominant. Thus, when minute doses of epinephrine are injected intravenously in animals, only a fall in blood pressure may occur, especially if vascular tone is already high. In man, subcutaneously administered epinephrine uniformly causes a fall in diastolic pressure due to vasodilatation. The "after-congestion" noted in mucosae after the disappearance of vasoconstriction due to the local application of epinephrine is accounted for by the vasodilator component in the drug. Finally, the phenomenon of *epinephrine-reversal* by ergotoxine is evidence that the compound can produce vasodilatation and a fall in blood pressure when the circumstances are propitious.

When ergotoxine or ergotamine is administered to an animal in sufficient dosage before epinephrine is injected, a rise in blood pressure no longer occurs. Instead, the pressure may fall markedly, a phenomenon known as *epinephrine-reversal* (Figure 40) (page 340). This effect of certain ergot alkaloids extends to responses other than the pressor action of epinephrine and was thoroughly investigated by Dale in 1906. It is believed that ergot paralyzes the receptive mechanisms of the smooth muscles of blood vessels responding to the excitatory component of epinephrine without influencing the receptive mechanisms responding to the inhibitory or vasodilator component. This property of ergot is discussed elsewhere and the use made of it in constructing the theory of sympathin has already been mentioned. The phenomenon of epinephrine-reversal, although for years one of considerable academic interest, has no therapeutic implications. Certain other sympathomimetic agents manifest a reversal of excitatory responses after ergotoxine or ergotamine.

Cardiac Effects. Epinephrine stimulates the heart by a direct effect on the myocardium and the conduction tissue. The rate is accelerated and the rhythm often altered. Cardiac systole is more forceful, the work of the heart is increased and cardiac output is enhanced. Oxygen consumption of the heart muscle is markedly elevated. These responses, reported by many investigators employing widely different experimental technics, leave little doubt that epinephrine is a powerful cardiac stimulant.

In addition to the tachycardia caused by epinephrine, evidence of increased myocardial irritability is often noted. The drug speeds auriculoventricular conduction, decreases the grade of A-V block occurring as a result of disease, drugs or vagal stimulation, and excites the idioventricular pacemaker in patients with complete heart block. Premature systoles of ventricular origin occur and may herald more serious types of ventricular rhythms. When other factors affecting cardiac irritability are present, such as anesthesia or disease, epinephrine is particularly likely to precipitate ventricular rhythms such as extrasystoles, tachycardia and even ventricular fibrillation. The dangers and precautions incident to the endogenous release of epinephrine or the use of the drug during anesthesia with certain agents are presented in detail elsewhere (pages 61, 93) (*see* Meek, 1940).

The effect of epinephrine on the *electrocardiogram* in animals has received considerable attention. For example, in unanesthetized cats receiving the drug intramuscularly, marked displacement of the S-T segment above or below the isoelectric level occurs. These changes can be abolished by nitroglycerin. Milles and Smith (1937) injected epinephrine into the saphenous vein or directly into the coronary artery in dogs. The minimal effect noted was a decrease in amplitude of the T wave. More marked cardiac action of the drug was manifested in a diphasic form of and directional changes in the T waves, deviation of the S-T segment from the isoelectric line, ventricular extrasystoles, and occasionally ventricular fibrillation. Inasmuch as direct measurements showed that the coronary flow was increased during the period when epinephrine was altering the electrocardiogram, the authors concluded that the electrical changes, which simulate those encountered in patients with angina pectoris, must be due to a relative myocardial anoxia caused by the increased demands for oxygen of the epinephrine-stimulated myocardium. This conclusion is in keeping with the known accelerated consumption of oxygen by heart muscle and the increased amount of cardiac work after epinephrine.

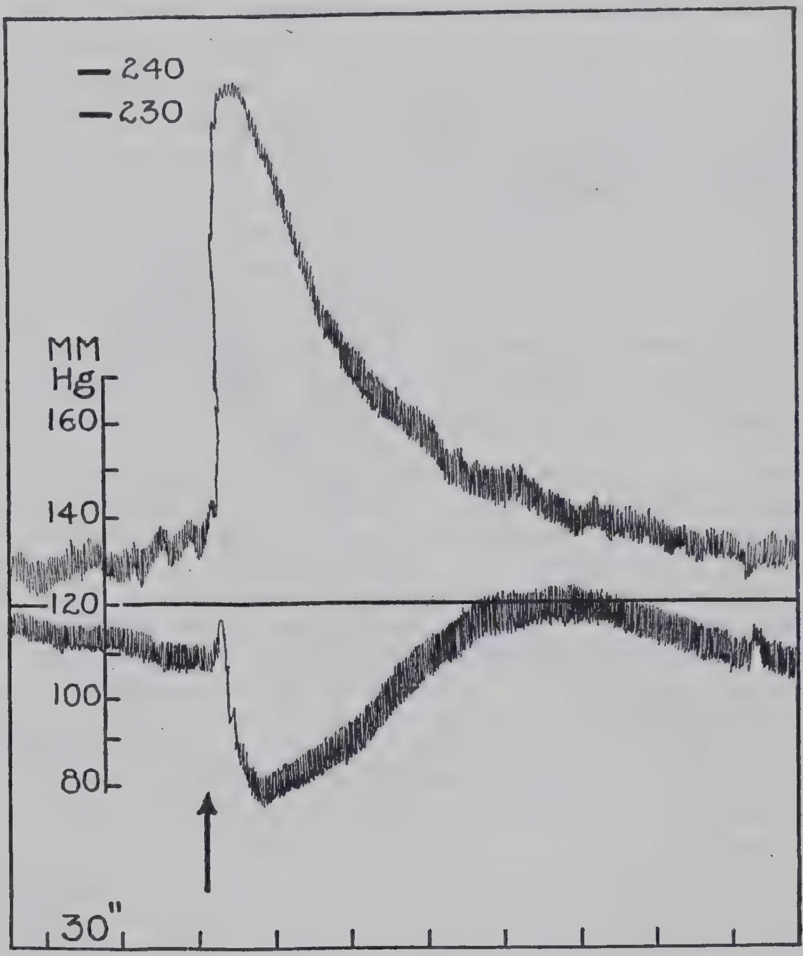

FIGURE 40. *The reversal by ergotoxine of the pressor response to intravenous epinephrine in a pithed cat.*

The upper tracing shows the effect of an injection of 0.025 mgm of epinephrine on the carotid blood pressure. The lower tracing depicts the fall in blood pressure which occurs after the injection of epinephrine (0.1 mgm) when 10 mgm of ergotoxine are previously administered. (After Dale, 1913. Courtesy of the *Journal of Physiology*.)

Vascular Effects. The chief vascular action of epinephrine is exerted on the smaller arterioles, although capillaries, veins and larger arteries also respond to the drug. Various vascular beds react differently. The vessels of the *skin* and *mucosa* are constricted and this is obvious after local injection or application as well as after systemic administration of the drug. Cutaneous vasoconstriction caused by epinephrine endogenously released from the adrenal medulla accounts for the expressions "pale with fright" and "white with anger." The blood vessels of *skeletal muscles* are dilated by epinephrine, a matter of importance in the economy of the body when flight or fight is necessary. The *splanchnic bed* is constricted by the drug. The *cerebral* and *retinal* vessels are also constricted by epinephrine and the *pulmonary vessels,* although less responsive to vascular agents than other vessels, tend to contract. The *glomerular arterioles* of the kidney constrict after epinephrine but the resulting effect on urine formation depends on the relative intensity of the effects on the afferent and efferent arteriolar limbs. If the predominant action of the drug is on the afferent arteriole, antidiuresis is likely to occur whereas constriction of the efferent arteriole increases filtration pressure and produces diuresis.

The response of the *coronary arteries* to epinephrine depends upon the species being examined and the technic employed. Both constriction and dilatation have been reported to occur after the drug, but dilatation is the predominant response. Melville (1933) reported that both epinephrine and ephedrine caused vasodilatation of the coronaries and abolished the coronary vasoconstriction induced by posterior pituitary extract. Anrep and coworkers (1936), using a direct flow method, observed coronary vasodilatation after epinephrine and Gollwitzer and associates (1936) found that both sympathetic nerve stimulation and epinephrine resulted in increased coronary blood flow. Katz and coworkers (1938) noted that the coronary flow in isolated perfused cat hearts decreased in some preparations in response to epinephrine but increased in others. In 23 dog hearts, however, the drug caused only coronary vasodilatation, occasionally preceded by a transient vasoconstriction. Boyer and associates (1939) injected epinephrine directly into the coronary arteries in 16 dogs and in each case the result was an enhanced coronary flow during diastole which preceded and persisted after the elevation of blood pressure. The rate of flow during systole in most instances was decreased. Given intravenously, epinephrine produced an increase of from 10 to 20 per cent in coronary blood flow. Essex and collaborators (1940), using trained dogs with thermostromuhr units implanted on the coronary arteries, observed that epinephrine markedly increased coronary blood flow (occasionally over 200 per cent), the augmented flow being accompanied by an accelerated heart rate.

The response to epinephrine, however, cannot be employed as an index of the effects of sympathetic nerve impulses on the caliber of the coronary arteries. It is usually stated that the sympathetic nerve impulses cause coronary vasodilatation whereas vagal impulses cause vasoconstriction (Anrep and Segall, 1926; Kountz and associates, 1934; and others). This concept has recently been questioned by Katz and Jochim (1939) who found in the dog heart, an organ similar at least experimentally to the human heart, that vagal stimulation produced only vasodilatation but that stimulation of the sympathetic fibers elicited either vasoconstriction or vasodilatation. The only coronary vasoconstrictor fibers were thus adrenergic in character and ran in the sympathetic pathways (Katz and Lindner, 1939). This concept is important for the surgical treatment of angina pectoris, and it is interesting to note in passing that Raney (1939) has devised an operation for angina pectoris which brings relief from pain after preganglionic section of the efferent sympathetic outflow to the heart, the afferent sympathetic fibers being left largely intact. The procedure involves the section of the rami communicantes of the second to and including the fifth thoracic sympathetic ganglion and the cutting of the sympathetic chain between the fifth and sixth ganglia.

Cardiovascular Responses in Man. The cardiovascular responses in man observed after the administration of epinephrine have been studied by numerous workers. The results obtained by Blumgart (1932) and Starr and associates (1937) may be taken as representative. Blumgart injected 0.5 to 1.0 cc of a 1:1000 solution subcutaneously into 10 normal subjects under strictly basal conditions. The pulse rate increased from 12 to 24 beats per minute (average of 16) in eight of the 10 subjects, only two failing to develop a tachycardia. The systolic blood pressure rose in all instances from 10 to 70 mm of mercury, the average being 38. The diastolic pressure remained unchanged in three subjects but *fell* from five to 35 mm of mercury in the remaining, an average of 14. Thus the pulse pressures in the group as a whole increased markedly from an average of 46 mm of mercury to 94. The speed of blood flow was accelerated in every subject, the increase varying from 30 per cent to 143 per cent and averaging 76. The peripheral blood flow, as gauged by the arm to heart circulation time, was enhanced in eight of the 10 individuals, an average of 105 per cent. In two, the circulation time was slightly decreased.

Starr and coworkers obtained essentially similar results in a careful study of six patients, several of whom had cardiovascular disease. Epinephrine was injected subcutaneously in an average dose of 0.7 cc of a 1:1000 solution. The results in comparison with the responses to ephedrine are shown in Table 22. The pulse rate, cardiac output, stroke volume, and left ventricular work per minute and per beat were all increased significantly. The systolic pressure rose somewhat but particularly noteworthy is the *fall* in diastolic pressure and the decreased peripheral vascular resistance. These facts indicate that epinephrine is a powerful cardiac stimulant in man and that after subcutaneous injection the diastolic pressure usually falls due to the vasodilatation in certain vessels predominating over the vasoconstriction which undoubtedly occurs in other areas. Apparently, when absorbed slowly from hypodermic sites of injection, the ability of epinephrine to produce vasodilatation takes precedence over constriction.

Table 22

CARDIOVASCULAR, RESPIRATORY AND METABOLIC EFFECTS OF EPINEPHRINE AND EPHEDRINE IN HUMAN SUBJECTS UNDER BASAL CONDITIONS

	Epinephrine Hydrochloride * (0.7 Cc [1:1000] Subcutaneously)		Ephedrine Sulphate ** (53 Mgm Subcutaneously)

Starr, Gamble, Margolies, Donal, Joseph and Eagle, 1937.

When epinephrine is injected *intravenously* in man, both the systolic and diastolic pressures rise markedly, optical manometric methods showing that the blood pressure sometimes reaches levels of 400/300 mm of mercury for a brief period. Due to inertia, these high tensions cannot be recorded accurately with mercury manometers. Great care must therefore be exercised to avoid the error of injecting epinephrine into a vein when subcutaneous injection is desired Cerebrovascular hemorrhages have occurred from this accident.

The ability of epinephrine to cause changes in the *electrocardiogram* and to induce attacks of *pain of cardiac origin* has been studied by several investigators both in normal persons and in those with angina pectoris. Clough (1919) observed that epinephrine decreased the T wave in all leads in the majority of normal persons and in patients with "irritable" hearts. Several clinical reports have indicated that patients with angina pectoris are likely to develop typical anginal attacks after injection of epinephrine. Thus, Levine and coworkers (1930) noted that one cc of a 1:1000 solution of the drug given subcutaneously resulted in typical pain in all but one of 11 patients with angina pectoris, and that the T wave increased slightly in amplitude. In 10 control patients of the same age group but without angina pectoris and in a second control group of 10 normal young adults, anginal pain did not occur and the T wave in Lead II showed a tendency to decrease. These investigators suggested that the drug might prove serviceable as a diagnostic test for angina pectoris in patients in whom the diagnosis is uncertain. Katz and collaborators (1932), however, point out that the electrocardiographic changes noted are not characteristic of those occurring during spontaneous angina pectoris, a depression of the S-T segment being the usual finding and changes in the T wave being variable. Katz and associates noted precordial distress in two of six normal persons after injections of epinephrine and that three of six patients with angina failed to develop pain after the drug. The most characteristic change produced by epinephrine in the electrocardiogram in the patients with angina was a deviation downward of the S-T segment similar to that noted during spontaneous attacks of angina. This finding, however, was not constant and occurred in an individual without angina. The T wave was decreased in amplitude in practically all cases, normal as well as those with angina pectoris. It was concluded that the production of pain by epinephrine is not a reliable index of angina pectoris and that the electrocardiographic changes are not pathognomonic for the syndrome. The test also cannot be advised because of the severe reactions which may occur.

Respiratory Effects. Epinephrine lacks the property of stimulating the respiratory center which characterizes certain other sympathomimetic amines, and consequently has no appreciable direct effect on the respiratory rate. When the drug is given intravenously to animals, a period of apnea may follow ("epinephrine apnea") due to the reflex inhibition of respiration caused by the increased pressure in the carotid sinus and cardio-aortic area (Heymans and Bouckaert, 1930). The drug can influence respiration in other ways, however, particularly through relaxation of the bronchial musculature. This antispasmodic action is clearly evident when the bronchial muscles are in a state of heightened contraction or spasm due to vagal stimulation, drugs such as pilocarpine, choline esters, etc., or disease such as bronchial asthma. Despite the theoretical reasons why atropine should be ideal in counteracting bronchial spasm resulting from vagal stimulation, epinephrine is markedly superior in causing immediate and effective relaxation. It is evident from Figure 41 that epinephrine is not only effective in counteracting vagal-induced bronchial constriction but that during the period of its action further cholinergic stimulation may be entirely without effect. No more potent bronchodilating agent than epinephrine is available to the physician. In addition, epinephrine may increase vital capacity by lessening the edema of congested bronchial mucosa.

Respiratory volume may be markedly increased by the injection of epinephrine even when patients are not suffering primarily from disturbances in respiratory exchange. Thus, Starr and associates noted in the experiments cited that respiratory minute volume was enhanced an average of 42 per cent in their six subjects, and that the rate of respiration increased 26 per cent (Table 22). In a study of the total pulmonary capacity and its subdivisions in five patients during acute attacks of bronchial asthma before and immediately after the subcutaneous injection of 0.75 cc of 1:1000 solution of epinephrine, Hurtado and Kaltreider (1934) observed that the decrease in the absolute and relative value of the vital capacity and the marked increase in the mid capacity and residual air which characterize the acute respiratory distress of bronchial asthma are rapidly alleviated by the drug. Thus, the vital capacity increases, the mid capacity and residual air are decreased and symptoms are thereby alleviated. These effects of epinephrine are graphically depicted in Figure 42. Essentially similar results have been reported by Means (1924) and Anthony (1930). Improved pulmonary function as indicated by increased vital capacity and maximum breathing capacity has also been reported to occur following the inhalation of vaporized epinephrine solution by patients with asthma and emphysema (Richards and coworkers, 1940).

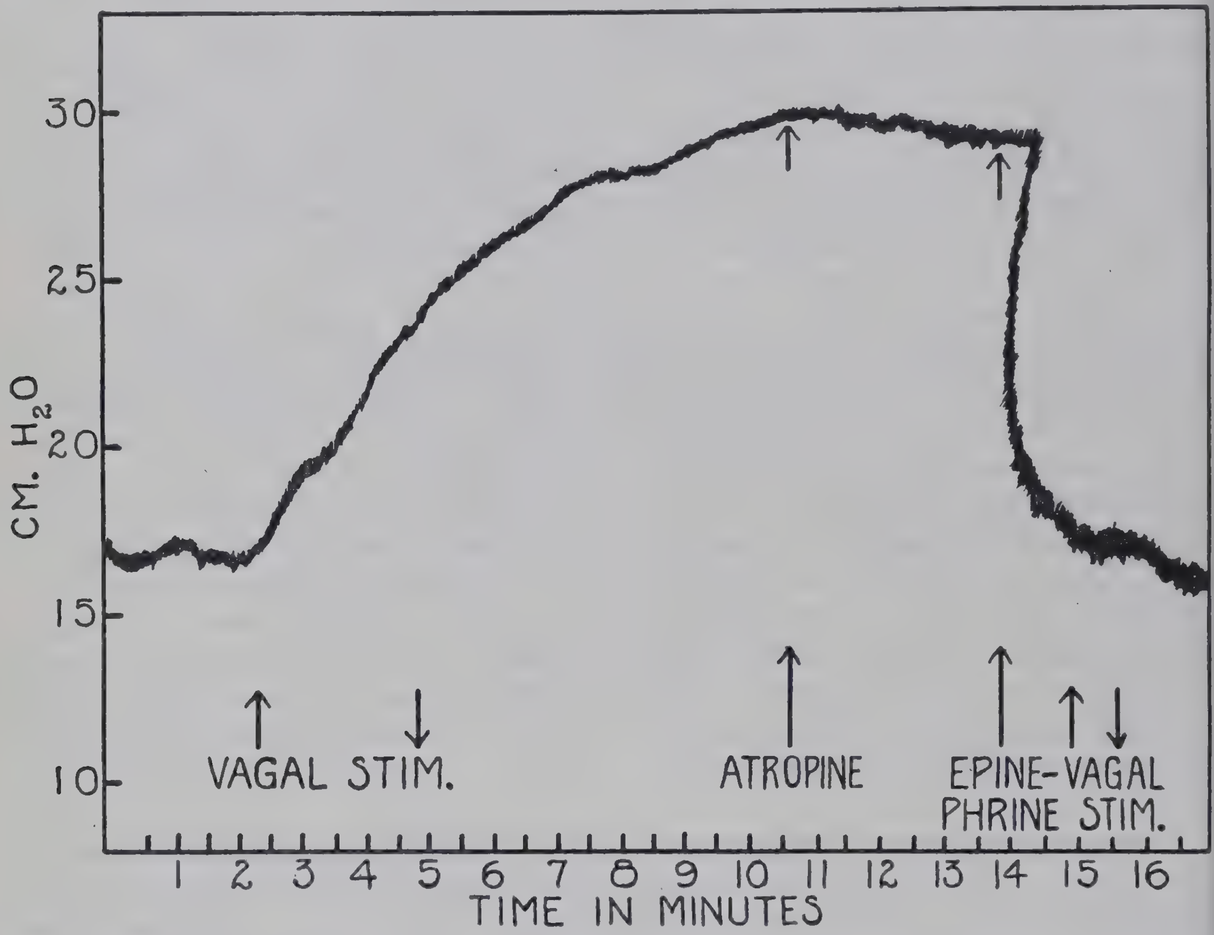

FIGURE 41. *The comparative value of atropine and epinephrine as bronchial antispasmodics.*

Perfused guinea pig lung. Bronchial spasm produced by stimulation of the vagus, and recorded by measuring the bronchial resistance in centimeters of water. Moderate amounts of atropine fail to relax the bronchial muscle, whereas epinephrine is immediately effective. During the period of action of epinephrine, further vagal stimulation is incapable of causing bronchial contraction. (After Thornton, 1932. Courtesy of the *Quarterly Journal of Experimental Physiology* and Sir Edward Sharpey Schafer's Trustees.)

Metabolic Effects. Epinephrine is a metabolic stimulant, increasing oxygen consumption. It promotes the combustion of carbohydrate and therefore the respiratory quotient rises. Body temperature is also increased. The basal *metabolic rate* in man is elevated by the subcutaneous injection of average doses, Blumgart (1932) noting an increase of 16 per cent in six normal subjects and Starr and coworkers (1937) observing an increase of 30.4 per cent (Table 22). The calorigenic action is unrelated to stimulation of the thyroid. It may be due to a direct action of epinephrine on cellular oxidations, but it is said not to occur in hepatectomized animals.

The ability of epinephrine to elevate the *blood sugar* and to cause *hyperglycemia* and *glycosuria* is well known. These phenomena occur as a result of mobilization of sugar from the liver. The drug can thus relieve insulin hypoglycemia, provided the liver stores of glycogen are adequate. Epinephrine also reduces the muscle stores of glycogen. For this reason, when injected into a long-fasting animal, the drug may increase liver glycogen at the expense of the muscle glycogen. The influence of epinephrine on carbohydrate metabolism in mammals has been intensively studied by many investigators, especially by Cori and Cori (*see* review by Cori, 1931).

Action on Smooth Muscles. The effects of epinephrine on the smooth muscles of blood vessels and bronchi have already been described. The musculature of the *gastro-intestinal tract* is relaxed by epinephrine and that of the pyloric and ileocecal sphincters, as a rule, is contracted. Intestinal tone is diminished and the frequency and amplitude of peristaltic waves are decreased. The sphincters, however, may react in a variable manner to epinephrine, as they do to other autonomic drugs and to autonomic nerve impulses, depending on their level of functional activity at the time (page 466). The effects of epinephrine on the alimentary canal have no therapeutic applications because they are elicited only by doses which cause marked cardiovascular responses.

The musculature of the *splenic capsule* is contracted by epinephrine. This reduction in size of the spleen accounts for the increase in the number of red blood cells and the increase in blood viscosity observed in the peripheral circulation after administration of the drug. Contraction of the vascular spaces of the *bone marrow* may also contribute to the epinephrine-induced erythremia. The secretion of epinephrine provides a physiological mechanism for increasing the amount of circulating hemoglobin during acute anoxia, hemorrhage, etc.

The *detrusor muscle* of the urinary bladder is relaxed by epinephrine, the *trigone* and *sphincter* being contracted. The *uterine musculature* exhibits variable responses to epinephrine, dependent on the species examined, the time of the menstrual cycle or the state of gestation. Both the gravid and non-gravid uterus in many animals are stimulated, but in certain species the non-gravid uterus is relaxed. Uterine relaxation, for example, can be observed regularly in the non-pregnant cat (Figure 29), and the constancy of this response provides a means of identifying sympathin I. The human uterus is generally contracted by epinephrine, whether pregnant or non-pregnant, but this action is not marked and rarely, if ever, interferes with the use of the drug for other purposes, if needed, in pregnant patients. When tested *in vitro,* muscle strips from human uteri usually contract in response to epinephrine regardless of the day of the menstrual cycle at the time of hysterectomy (Miller and coworkers, 1937).

Miscellaneous Actions. Epinephrine has very little stimulating effect on the *central nervous system* and thus is not useful as an analeptic or as a central respiratory and vasomotor stimulant. Nevertheless, restlessness, apprehension, headache and tremor may occur in some individuals after therapeutic doses. The *secretory effects* of epinephrine on glands are negligible, secretion usually being inhibited as a result of the accompanying vasoconstriction (Table 17). Sweating and pilomotor responses are not seen in man after administration of epinephrine but may be quite marked in certain species of animals. Thus marked sweating occurs in the horse and sheep. *Mydriasis* is noted in human beings to whom epinephrine is given only when the radial fibers of the iris are denervated as a result of interruption of the superior cervical sympathetic nerve fibers or when the iris is sensitized by thyroxin, as in hyperthyroid individuals.

Absorption, Fate and Excretion. *Absorption.* Epinephrine is not absorbed from the enteric mucosa due to its destruction by the gastro-intestinal juices. Absorption occurs from the subcutaneous tissues and can be hastened by massage of the injection site. Absorption is appreciably delayed by suspending the drug in an oil. Epinephrine administered intramuscularly is more rapidly absorbed than from subcutaneous tissue. Although systemic effects are not observed after local application of the drug to mucosal surfaces, marked local vasoconstriction is observed. When strong solutions (one per cent) are nebulized and inhaled, the actions of the drug are restricted to the respiratory tract, and although systemic reactions may occur, these are usually mild unless large amounts or stronger solutions are employed.

Fate. The exact fate of epinephrine in the body is unknown. The drug is rapidly destroyed in the body within a few minutes and ligation of the renal vessels, hepatectomy, etc., do not affect the rate of inactivation. It appears that epinephrine is inactivated in the tissues by oxidation. The enzyme thought to be responsible for the oxidation has been termed "amine oxidase" (Blaschko and coworkers, 1937; Blaschko, 1938; Richter, 1937). This oxidase apparently catalyzes the destructive deamination of a large number of different types of amines including certain sympathomimetic amines related to epinephrine (tyramine, phenylethylamine, synephrin), but not others (ephedrine, benzedrine). It is distinct from both amino acid oxidase and histaminase. The enzymatic oxidation of epinephrine (by peroxidase) results in the simultaneous loss of excitatory and inhibitory properties of the molecule (Blaschko and Schlossman, 1940).

Amine oxidase is definitely not specific for epinephrine and probably represents the system mainly responsible for the detoxication of amines in the body. The results of Richter and Tingey (1939) cast some doubt on the rôle played by amine oxidase in the oxidative destruction of epinephrine and sympathin in the tissues. Evidence from *in vitro* experiments appears to indicate that the rate of oxidation by this enzymatic system is not sufficiently rapid to account for the speed of disappearance of epinephrine *in vivo.* Amine oxidase exists especially in the liver and intestine (in ruminants), suggesting that it is concerned primarily with the detoxication of amines formed by bacterial action in the gut. Until information is obtained concerning the distribution of amine oxidase at adrenergic nerve endings similar to the data existing for the concentration of cholinesterase at cholinergic nerve endings, any conclusion concerning the physiological rôle of amine oxidase in the destruction of epinephrine and sympathin *in vivo* must be held in abeyance.

Excretion. Little is known of the excretion of epinephrine or its breakdown products. *Protocatechuic acid* has been isolated from the urine of rabbits injected with epinephrine and this may represent the inactive oxidation product (Weinstein and Manning, 1937).

Preparations. A variety of preparations of epinephrine is available to the physician and the terminology employed is often confusing. *Epinephrine* is the official U.S.P. term, *Adrenaline,* the B.P. term. Unfortunately, certain trademarked names (*e.g.,* "adrenalin," "suprarenin") are used synonymously with epinephrine in common medical parlance.

Epinephrine, U.S.P., B.P. (*Adrenaline*), is the levorotatory form of methylaminoethanolcatechol. It is a white or light brown, microcrystalline, odorless powder which gradually darkens on exposure to air. The drug is slightly soluble in water and in alcohol and is insoluble in the usual organic solvents as well as in fixed or volatile oils. The U.S.P. and B.P. do not specify the source of the drug, which may be obtained from the suprarenal medulla of domestic animals or prepared synthetically. Epinephrine forms water-soluble salts with acids. The drug is unstable in alkaline solution due to oxidation. Oxidizing agents turn epinephrine a red, pink or violet color which changes to brown. The drug should be preserved in air-tight containers and protected from light. Only levorotatory epinephrine is employed clinically. The d-l (racemic) synthetic form is only one-half and the dextrotatory compound is only one-eighteenth as potent as the official drug.

Epinephrine is usually administered in the form of its soluble salts. Epinephrine base, however, has been incorporated as a suspension of powdered epinephrine in peanut oil (*Epinephrine in Oil*) in a concentration of 2.0 mgm per cc (0.2 per cent solution) for intramuscular (preferable) or subcutaneous injection when prolonged systemic effects are desired. The preparation is not official but is described in N.N.R. Epinephrine in oil is sometimes referred to as "slow epinephrine."

Solution of Epinephrine Hydrochloride, U.S.P., B.P. (*Solution of Adrenaline Hydrochloride*), is a 1:1000 sterile solution in distilled water for parenteral administration. The solution is a nearly colorless, slightly acid liquid which withstands a short period of boiling and keeps fairly well when undiluted and aseptic. It gradually turns dark on exposure to air and light and deteriorates in a few hours when diluted. The solution must be rejected if the color has changed or a precipitate has formed. An acceptable preservative is added (usually 0.5 per cent chlorbutanol or sodium bisulfite) and the solution is usually dispensed in sterile ampules containing one cc (1.0 mgm). Five, 10 and 30 cc vials are also marketed. The U.S.P. requires assay of the solution by means of the blood pressure response in the dog.

Epinephrine hydrochloride is only official in the form of the 0.1 per cent aqueous solution described. However, other preparations are available for use. The N.N.R. includes *hypodermic* tablets of the drug, each containing 0.33 or 1.0 mgm, so that addition of 0.33 or 1.0 cc of water, respectively, will yield a 1:1000 solution. Epinephrine bitartrate and epinephrine borate are also marketed in tablet form and in solution. Epinephrine hydrochloride is also available in a more concentrated solution than the official one. Thus a 1.0 per cent solution in 0.9 per cent sodium chloride is available for inhalation therapy of asthma—*Solution of Epinephrine Hydrochloride 1:100* (*N.N.R.*)—supplied in five cc ampules. This preparation must not be confused with the one used for parenteral injection and is 10 times as strong. Finally, epinephrine hydrochloride is marketed in the form of an *inhalant* (1:1000 in glycerin), *ointment* (1:1000 in petrolatum) and *suppository* (1:1000 in cacao butter).

Routes of Administration and Dosage. Epinephrine is inactive when taken *orally* and is used by this channel only when the local effects on the gastric mucosa are desired. The *subcutaneous* route is the one most frequently employed. A 1:1000 (0.1 per cent) solution is used. The usual adult dose ranges from 0.2 to 0.5 cc (0.2 to 0.5 mgm). Epinephrine in oil (0.2 per cent solution) may also be adminstered subcutaneously, although the intramuscular route is preferable when continued administration is necessary. The dose for adults is 0.75 cc to 1.5 cc (1.5 to 3.0 mgm). The advantages of epinephrine in oil are discussed under the use of the preparation in the treatment of asthma. The *intravenous route* is rarely employed. If the drug is given by vein, it must be greatly diluted and given *very* *slowly*. The dose varies with the results desired, but usually is not greater than 0.25 mgm. *Intracardiac* injection is occasionally employed in extreme emergencies for purposes of resuscitation. Administration of epinephrine by *inhalation* is advantageous under certain circumstances. A 1.0 per cent solution is employed. Epinephrine may be applied *locally* to mucous membranes or abraded surfaces in the form of an aqueous solution, inhalant, suppository or ointment, a 1:1000 concentration generally being employed.

Toxicity, Precautions and Contraindications. Certain mild untoward reactions may occur from the administration of epinephrine. These consist of fear, anxiety, tenseness, restlessness, throbbing headache, tremor, weakness, dizziness, respiratory difficulty, and palpitation. The effects subside rapidly with rest, quiet and reassurance, but nevertheless the patient is often alarmed and probably should be forewarned. Hyperthyroid individuals are particularly susceptible to the untoward responses noted after epinephrine.

More serious accidents consist of cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental intravenous injection of epinephrine may result in cerebral hemorrhage due to the sharp rise in blood pressure. Flexner and Schneider (1938) record subarachnoid hemorrhage in a young woman following the subcutaneous injection of 0.5 cc of a 1:1000 solution of the drug and Keeney (1939) has observed a complete right-sided hemiplegia and loss of vision in the right field in a young man after a similar dose injected during an asthmatic attack. Obviously, care should be exercised in using the drug in patients with advanced cerebral arteriosclerosis.

Ventricular arrhythmias may follow the administration of epinephrine and if ventricular fibrillation develops it is usually fatal. This arrhythmia is particularly prone to occur if the drug is used unwisely during surgical anesthesia or in individuals with organic heart disease. Patients with long-standing bronchial asthma and a significant degree of emphysema who have reached the age in which degenerative heart disease is prevalent must be given epinephrine only with considerable caution (Smith and Paul, 1938). In patients suffering from medical or surgical shock, the drug may accentuate the underlying disorder (pages 588). Those with hypertensive heart disease or hyperthyroidism are prone to be hypersusceptible to the pressor effect of epinephrine. Anginal pain due to epinephrine frequently occurs in patients with angina pectoris (Levine and coworkers, 1930; Cottrell and Wood, 1931; Katz and associates, 1931). This is probably due to the great increase in cardiac work resulting from the actions of the drug. In psychoneurotic individuals, existing symptoms are often markedly aggravated by epinephrine (Kraines and Sherman, 1940).

Therapeutic Uses

Epinephrine has a wide variety of clinical uses. In general, these are concerned with the actions of the drug on the blood vessels, heart and bronchial muscles.

Clinical Use of Vascular Effects. *Control of Hemorrhage.* The vasoconstrictor action of epinephrine is useful in the control of superficial hemorrhages of the skin and mucous membranes. The drug may be employed in freshly prepared solutions ranging in concentration from 1:50,000 to 1:2000 and applied directly to accessible bleeding surfaces in the form of a spray or on cotton or gauze pledgets. It is useful in operations on the nose, throat and larynx where considerable clearing of the operative field is obtained by diminution of hemorrhage and shrinkage of mucous membranes. The local hemostatic action of epinephrine is effective only against bleeding from smaller arterioles and capillaries, and hemorrhage from larger vessels or venous oozing is not readily controlled. Obviously there is no rationale for the systemic administration of epinephrine in internal hemorrhages. The drug has been given orally in gastric hemorrhage, the action, if any, being confined locally to the mucosa. Unless the bleeding is from very small mucosal vessels the benefit to be derived from this practice is highly questionable. Epinephrine solution, however, has been given orally for the relief of protracted vomiting due to gastritis, as in the bilious type of pernicious malaria. Benefit is probably due to shrinkage of the hyperemic and congested gastric mucosa as a result of local vasoconstriction.

Congestion of the Nasal Mucosa. Epinephrine causes marked vasoconstriction and blanching when its solutions are applied to the nasal mucosa. It is thus useful in the treatment of the mucosal congestion accompanying hay fever, allergic rhinitis, acute coryza, sinusitis, etc. Oily solutions of epinephrine are more persistent in action. A phase of after-congestion often occurs when the vasoconstrictor effect has disappeared. The significance of this has been explained. The short duration of action of epinephrine and the tendency to cause after-congestion limit its value for shrinkage of the nasal mucosa. Other sympathomimetic agents have been found more serviceable for this purpose. Epinephrine has the advantage, however, of being non-irritating. Thus its solutions are useful in overcoming marked vascular congestion of the conjunctiva.

Use with Local Anesthetics. Epinephrine is widely employed in solutions of local anesthetics. By causing vasoconstriction, the drug limits the absorption of the local anesthetic and thus prolongs the duration of anesthesia, decreases the amount of anesthetic needed and lessens the danger of systemic toxicity. Furthermore, hemorrhage from the ensuing surgical procedure is decreased. The resulting bloodlessness of the operative field, however, may make adequate surgical hemostasis more difficult because small vessels, constricted by epinephrine, may escape detection. These are potential bleeders when the vasoconstrictor effect of epinephrine has worn off and after-dilatation occurs. Epinephrine is particularly indicated when procaine and other synthetic congeners are injected because, unlike cocaine, these anesthetics lack a vasoconstrictor action. Concentrations of epinephrine of from 1:100,000 to 1:20,000 are incorporated in the anesthetic solution. Further details of the combined use of epinephrine and local anesthetics are discussed in connection with the latter drugs.

Shock. The mechanism of the shock syndrome is described in detail on page 586 and it is there pointed out that the primary disturbance is a sharp discrepancy between the amount of circulating blood volume and the volume capacity of the circulatory system. Epinephrine has little place in the therapy of shock because the arterioles are already constricted maximally in a reflex attempt to maintain the blood pressure. Indeed, the drug may accentuate the basic pathological physiology of the syndrome by further increasing the degree of tissue anoxia through constriction of arterioles (*see* also epinephrine in nitrite syncope). Much safer and more effective measures are available for the management of shock than the use of vasopressor drugs.

Clinical Use of Cardiac Effects. *Heart Block with Syncopal Seizures.* In *Stokes-Adams disease,* epinephrine may relieve the syncopal seizures and give symptomatic relief by virtue of its cardio-accelerating property. Before using epinephrine in patients with complete auriculoventricular dissociation, however, one must make certain that the syncopal attacks are due to periods of asystole or marked bradycardia rather than to short runs of abnormal ventricular rhythms of a prefibrillation type, in which event epinephrine may precipitate fatal ventricular fibrillation. Caution is also required in patients with hypertension, marked arteriosclerosis or other organic cardiovascular lesions.

The usual dose is 0.3 to 0.6 cc of a 1:1000 solution injected subcutaneously and repeated at intervals as needed. Somewhat larger amounts of epinephrine in oil may also be employed for more prolonged effects. Larger doses than those providing relief do not result in greater acceleration of the idiopathic ventricular rate. Intravenous injection of epinephrine is not to be used, except perhaps when death appears imminent due to prolonged asystole. Under such circumstances, the drug may be life-saving. The good effects of therapy may persist for many hours and the cardiac rate may be maintained above 30 beats per minute, sometimes as high as 50 or 60, for days at a time with epinephrine therapy. Epinephrine speeds the ventricular rate either by diminishing the grade of auriculoventricular block, or, more commonly, by stimulating the idioventricular pacemaker. The block is not abolished as a rule, although normal sinus rhythm may be restored in rare instances.

Both the auricular and ventricular rates are increased by epinephrine in complete heart block. Whereas the effect of the drug on the rate of auricular contraction bears no relation to the initial auricular rate, there is a direct correspondence between the drug-induced acceleration of the ventricle and the initial idioventricular rate. The slower the original ventricular rate, the more pronounced is the accelerating effect of epinephrine. When the initial rate is high, epinephrine has little further action on it. This is the exact reverse of the situation obtained in the use of atropine in complete heart block (page 476) and again illustrates that the responses of the heart to drugs are often conditioned by the level of functional activity existing at the time.

Resuscitation in Cardiac Arrest. Epinephrine is too often looked upon as an effective agent in reviving patients apparently dead from drowning, electric shock, anesthetic accidents, etc. While it is true that the drug occasionally produces dramatic results, much more often it fails entirely. This is due either to the fact that the arrested heart is beyond resuscitation or to the precipitation of ventricular fibrillation by the large doses of epinephrine administered intravenously or intracardially. If heart sounds are still audible, small doses of epinephrine (0.05 to 0.2 cc of a 1:1000 solution) may be diluted and injected very slowly intravenously. If heart sounds are unobtainable, intracardiac injection of 0.5 cc may be performed. When death is imminent, heroic measures are justified despite the potential risk of ventricular fibrillation. If asystole occurs during the early phase of inhalation anesthesia, it is quite likely that ventricular fibrillation already exists and little benefit can then be expected from injecting epinephrine. Cardiac massage, if possible, artificial respiration and other emergency measures should also be employed.

Acute Cardiac Failure. Epinephrine has occasionally been employed as an emergency stimulant in the treatment of acute cardiac failure. More often than not, however, circulatory failure is peripheral in nature and comes under the category of shock, rather than being due to primary weakness of the myocardium. Under these circumstances, the measures employed in shock therapy are to be instituted. Nevertheless, the mechanism of acute cardiac failure is often complicated, as in the type occurring during the course of an acute infectious disease, and there may be present a distinct factor of acute myocardial decompensation as well as vasomotor paralysis or capillary dilatation due to toxic agents. After the usual measures employed in circulatory collapse have been instituted and if epinephrine is still decided upon as a myocardial stimulant, it should be administered subcutaneously (0.25 to 0.5 cc of a 1:1000 solution). Occasionally, the drug has been added in very small amounts to the intravenous solutions used to restore blood volume. It requires considerable discretion to determine whether epinephrine is required in emergencies of this sort, and one must weigh carefully the rôle played in the acute circulatory failure by the myocardial decompensation as opposed to the peripheral circulatory factors, remembering that "more get well than are cured."

Cardiac Asthma. In cardiac asthma (dyspnea due to left ventricular weakness) therapy is designed to restore myocardial compensation and relieve the strain on the left ventricle. In the acute form of the disorder, such as severe attacks of paroxysmal nocturnal dyspnea, in addition to the use of morphine, theophylline, nitroglycerin, cardiac glycosides, intravenous hypertonic glucose, phlebotomy and other physical measures, etc., epinephrine may occasionally be used with caution as an adjunct. This is particularly true in cases where there appears to be an added element of bronchial spasm contributing to the dyspnea and asthmatic breathing. From 0.2 to 0.3 cc of a 1:1000 solution may be injected subcutaneously. The drug is definitely contraindicated in patients with coronary thrombosis and angina pectoris. Although hypertensive cardiovascular disease is usually the syndrome underlying cardiac asthma, the judicious use of epinephrine does not seem further to elevate the blood pressure and a paradoxical fall with relief of the asthma may even occur. It should definitely be appreciated, however, that epinephrine is of minor value in comparison with the more usual and effective measures listed above. Benefit from the drug can be expected only when it is used wisely in those cases where bronchial spasm is superimposed on the basic pulmonary vascular congestion due to the left ventricular failure. The use of epinephrine carries with it clear contraindications in patients with heart disease, and the drug may be harmful in cases of frank pulmonary edema.

Allergic Disorders. *Bronchial Asthma.* Epinephrine occupies an unrivaled place among drugs used in the symptomatic therapy of bronchial asthma. It is a more potent bronchial antispasmodic than any of its congeners and the mechanism by which it affords relief has already been outlined. Likewise the changes in pulmonary ventilation occurring after injection of the drug during the acute asthmatic attack have been described (Figure 42). Regardless of the manner in which epinephrine is administered, the smallest effective dose should be employed because patients with bronchial asthma occasionally develop *tolerance* to the compound if it is repeated often. Increasingly larger doses may then be needed to give relief and these may cause marked side-effects. *Epinephrine refractoriness* is not uncommon in protracted severe cases and in status asthmaticus. Although a true tolerance develops toward the bronchial antispasmodic action of epinephrine, addiction is not observed. Psychic dependence (habituation) may occur, however, and the patient is apprehensive of the withdrawal of the drug due to fear of the return of the asthmatic attack. The use of epinephrine is reserved for the relief of acute paroxysms and other measures are employed in mild attacks or for preventive therapy.

Epinephrine may be administered in several different ways. The *aqueous solution* (1:1000) may be injected *subcutaneously.* The dose depends on the severity of the attack, the age of the patient and the response to previous therapy with epinephrine. The usual dose for adults varies from 0.2 to 0.5 cc (children, 0.1 to 0.3 cc). This may have to be repeated at 10 or 15 minute intervals until relief is afforded, benefit usually appearing within three to five minutes after the injection. Tremors and nervousness often herald the approach of cessation of the paroxysm. Because the drug impedes its own absorption from the subcutaneous tissue due to vasoconstriction, vigorous massage over the site of injection may give relief from a return of the dyspnea by promoting absorption of locally retained epinephrine. Occasionally, this procedure is effective in a lessened degree even an hour or more after the injection.

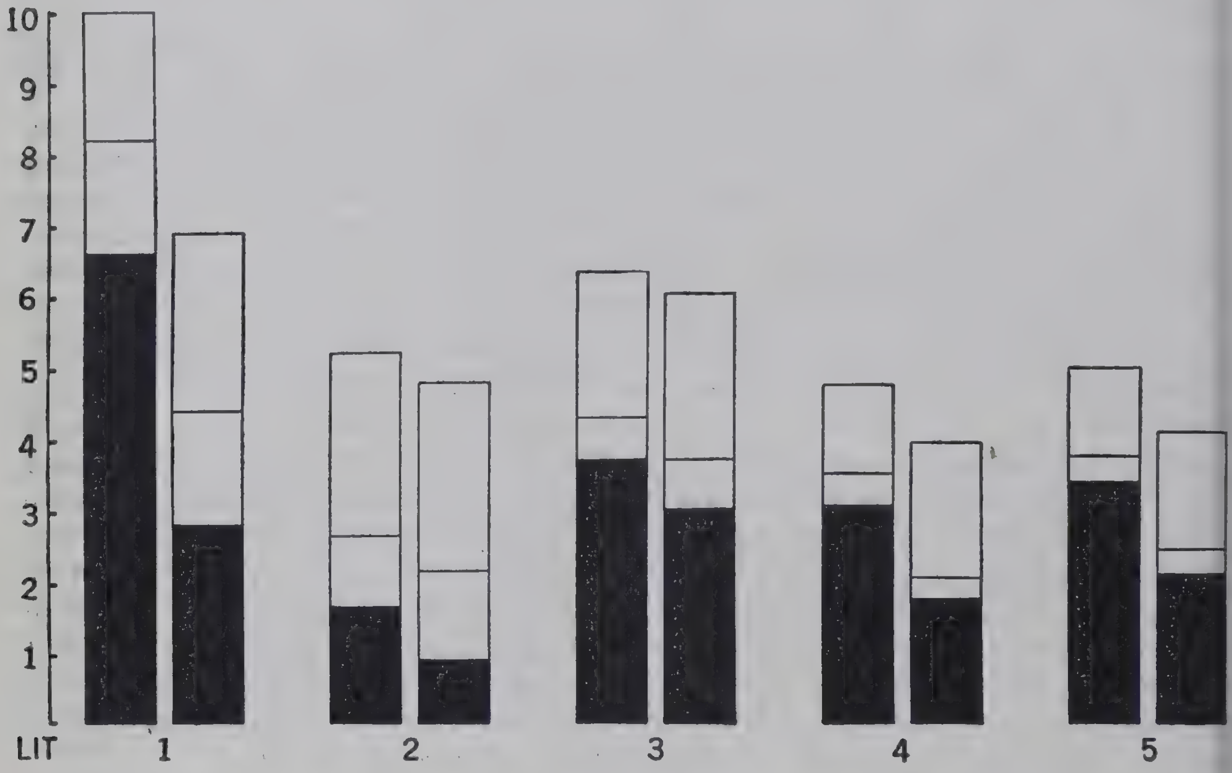

FIGURE 42. *The effect of the bronchodilating action of epinephrine on the total pulmonary capacity and its subdivisions in patients during the acute respiratory distress of bronchial asthma.*

The ordinate scale indicates volume of air in liters. Five cases are depicted, the left column in each pair indicating the status before therapy, and the right column the status soon after relief was obtained by the subcutaneous injection of 0.75 cc of a 1:1000 solution of epinephrine hydrochloride (case 4 received 0.5 cc). The black area in each column represents the residual air; the white space above is the vital capacity. The line dividing the vital capacity is the mid-capacity level. At the height of the acute asthmatic attack, there is a decrease in the absolute and relative value of the vital capacity, and a marked increase in the mid capacity and residual air. A few minutes after the administration of epinephrine, the vital capacity increases and there is a marked decrease in the mid capacity and residual air, these changes being associated with an amelioration or disappearance of the respiratory distress. (After Hurtado and Kaltreider, 1934. Courtesy of the *Journal of Clinical Investigation.*)

In patients refractory to epinephrine or in status asthmaticus, *intravenous injection* of the 1:1000 aqueous solution of epinephrine may be employed if the patient has failed to respond to the drug given by the hypodermic route. The technic is as follows: The needle is kept in the vein. After the hypodermic dose that is known not to cause unpleasant symptoms has been injected *very slowly* intravenously, additional increments of 0.05 to 0.1 cc are administered every one-quarter to one minute, according to the response of the patient, until relief is obtained. Injections may have to be continued for 15 minutes or more. Some claim that relief invariably follows this treatment. The patient then falls into a deep sleep, often his first respite in days. It would seem safer, however, to employ other measures in refractory patients, such as *theophylline, helium* and *oxygen,* rectal anesthesia with *ether in oil* or *avertin,* or intravenous anesthesia with a *barbiturate,* in order to break into the severe asthmatic cycle. Once this is accomplished, the former susceptibility to small doses of epinephrine is usually restored.

Epinephrine in oil may be employed instead of the aqueous solution (Keeney and coworkers, 1938, 1939; Murphy and Jones, 1939; and others). The suspension should be given by the intramuscular route (deltoid or gluteal) if repeated therapy is needed; otherwise it may be injected subcutaneously. In patients with acute severe paroxysms, a preliminary subcutaneous injection of the aqueous solution may be needed prior to the intramuscular therapy, due to the delayed onset of action (15 to 30 minutes) of the latter. It is useless to administer epinephrine in oil if the aqueous solution has failed to give relief. The usual dose for adults with acute asthma is 0.5 to 1.5 cc; for children, 0.25 to 0.75 cc. The dose should not be repeated until the effects of the previous injection have disappeared. The action of epinephrine in oil persists much longer than does that of the aqueous solutions. Relief lasts from four to 24 hours, usually from eight to 16 hours, whereas the aqueous solutions frequently afford relief for only one hour. Obviously the advantage of the preparation is its prolonged action due to its slow rate of absorption, as compared with the often fleeting effect of the aqueous solution which necessitates repeated injections at short intervals. The systemic responses to epinephrine in oil are also milder as well as more protracted than those to epinephrine hydrochloride solution. For example, the hyperglycemia which follows epinephrine in oil persists eight or nine hours, whereas that following the aqueous preparation, though more marked, is over in about three hours. The cardiovascular responses to the drug in oil also persist eight or nine hours, as compared with 45 to 90 minutes for epinephrine hydrochloride (Keeney, Pierce and Gay, 1939). In a series of 70 patients receiving a total of 967 injections of epinephrine in oil, Keeney (1939) observed only one severe reaction to the oil and one to the epinephrine. A 23 to 25 gauge needle should be employed to lessen the possibility of rupturing small blood vessels and thereby hastening the absorption of the solution.

Epinephrine in oil is particularly valuable in patients with *chronic asthma* who usually respond well to the preparation, experiencing fewer attacks and requiring fewer injections. A dose of one cc frequently permits an entire night's sleep free of attacks. The precautions and contraindications attending the use of epinephrine in oil are the same as those outlined previously for aqueous solutions of epinephrine hydrochloride. Keeney has reported his results in a series of individuals with chronic asthma who required from five to 10 injections of 0.3 to 0.5 cc each of the aqueous solution each 24 hours for periods varying from three months to eight years. When placed on epinephrine in oil, these patients were relieved for from eight to 16 hours by a single injection.

Epinephrine may also be administered by *inhalation* for the relief of bronchial asthma. The technic of applying the drug directly to the bronchial mucosa in asthma is not new, having been first tried by Ephraim in 1910. (*See* Graeser [1939] for historical review.) Stronger solutions than the conventional 1:1000, however, were not employed until 1935 when Graeser reported his results in asthma with a 1:100 solution. The 1.0 per cent aqueous solution of epinephrine hydrochloride is used. Weaker solutions (1:200) are less effective and a two per cent solution (1:50) rarely gives more relief than the one per cent and causes much more frequent systemic effects, such as tremor, palpitation and headache. A special *all glass* nebulizer is needed, contact with metal being avoided, and considerable practice may be required to use the apparatus skilfully. The fine spray is inhaled at the very moment the bulb of the nebulizer is compressed in order that the solution may be properly distributed in the lungs. Special inhalation masks supplied with the nebulized solution by a motor driven pump are also available and are particularly useful for children. A spray of high density and consisting of droplets of extreme fineness (mistlike) is needed for best results and many failures are traceable to disregard of these technical factors, especially the choice of a nebulizer.

A simple technic for *continuous inhalation* of vaporized bronchodilator solutions for severe asthmatic states has been reported by Richards, Barach and Cromwell (1940). It consists in the use of a pressure tank of oxygen with the usual reducing valve to regulate flow, the outflow tube being attached to the vaporizer. Oxygen is run into the vaporizer at a rate sufficient to produce adequate vaporization. A flow of four to seven liters per minute vaporizes one cc of solution in three to 10 minutes. The patient simply holds the nozzle of the vaporizer to his oropharynx and breathes quietly. The advantages of this method over the hand-bulb are that it can be employed without effort on the part of the patient (a boon to those exhausted from a severe asthmatic attack), a larger amount of solution is brought into contact with the bronchial mucous membrane, and less irritating solutions than one per cent epinephrine (*e.g.*, one per cent neo-synephrin) may be administered effectively whereas they are useless with the hand-bulb vaporizer.

Exact dosage for epinephrine by inhalation cannot be stated. Several inhalations may be required to obtain relief when the hand-bulb is employed. With the aforementioned continuous inhalation technic, a single treatment consists in the inhalation of 1.0 to 2.0 cc of solution over a period of three to 10 minutes. Relief occurs approximately as rapidly as after the subcutaneous injection of the aqueous solution and before systemic effects on the cardiovascular or nervous system are prominent. The patient should be impressed with the necessity of avoiding overdosage. Swallowing of the epinephrine solution may cause epigastric pain and the patient should therefore be instructed to rinse his mouth after using the spray. A bright pink color may be observed in the mucus expectorated after the inhalation. This is due to a change in the color of the drug and the patient should be told not to mistake this for blood. Too frequent use may result in dryness of the throat and tracheal and bronchial irritation. Inhalation therapy may then have to be suspended for several days. Graeser (1935, 1936, 1939) has had wide experience with the inhalation therapy of asthma and has observed no untoward harmful effects from it. Naturally, the course of the disease is unaltered. Inhalation of epinephrine has also been employed for the relief of angioneurotic edema. The value of inhalation over injection therapy is obvious, but therapy should be instituted only under the supervision of a physician. Further clinical experience with this method and with epinephrine in oil are required before their comparative merits will be fully known.

Miscellaneous Allergic Disorders. Epinephrine occupies an important place in the therapy of a number of miscellaneous types of acute allergic disorders. It affords symptomatic relief in many cases of *giant urticaria, serum reactions, serum sickness* and *angioneurotic edema.* When angioneurotic edema threatens suffocation due to involvement of the larynx, the drug may be life-saving. Epinephrine affords surcease from the discomfort of itching, hives, swelling of the lips, eyelids, tongue, etc., and other allergic features of the syndromes listed above. In certain forms of *eczema-dermatitis,* the drug may also give symptomatic relief. When performing *skin tests* for hypersensitiveness to various food, pollen and other allergens, epinephrine should always be at hand for the control of acute untoward responses. When the *conjunctival test for serum hypersensitivity* is employed, the discomfort of positive reactions is readily controlled by a few drops of epinephrine solution instilled in the conjunctival sac. Epinephrine in oil may be employed in small doses for the symptomatic relief of *hay fever* (Keeney, 1939).

Miscellaneous Uses. Epinephrine is of considerable value for the control of *nitritoid crises* and associated angioneurotic phenomena occurring during the course of therapy with arsphenamines. A solution of the drug ready for immediate use should be at hand during the administration of any of the arsphenamines, and an intramuscular injection of 0.5 cc should be given at the first evidence of nitritoid symptoms. This usually results in prompt relief. The onset of *inoculation malaria,* if unduly delayed, can be hastened by the intramuscular injection of 0.5 mgm of epinephrine. A similar amount may be injected in the event of a spontaneous termination of the malaria before therapy is completed. The mechanism of action is a contraction of the spleen and release into the circulation of blood containing the malarial plasmodia. In severe *hypoglycemia* due to hyperinsulinism or an overdose of insulin, epinephrine may be employed as an emergency measure to elevate the blood sugar pending the administration of carbohydrate. The drug is ineffective unless the liver contains adequate glycogen. For this reason and because the response varies considerably in different individuals, no great reliance should be placed upon the use of epinephrine in this emergency. A single subcutaneous injection of 0.5 mgm may be given but should not be repeated if ineffective. In *syncopal reactions* of the vagal and depressor variety due to *abnormal sensitivity of the carotid sinus,* epinephrine may have some beneficial effect (Weiss and associates, 1936). Other uses of epinephrine may be found by consulting the index.

CHAPTER 24

DRUGS STIMULATING STRUCTURES INNERVATED BY ADRENERGIC NERVES (SYMPATHOMIMETIC DRUGS)

II. EPHEDRINE, BENZEDRINE AND MISCELLANEOUS SYMPATHOMIMETIC DRUGS

EPHEDRINE

Source and History. Ephedrine is an alkaloid occurring in various plants belonging to the genus *Ephedra,* a gymnosperm related to the pines and firs. The genus is indigenous to the temperate and subtropical latitudes of Europe, Asia and America, and grows especially in Northern China, Northern India and Spain. In the United States, *Ephedra* plants grow along the Rocky Mountains but most of the naturally occurring types in this country do not yield the ephedrine alkaloid. The alkaloid and its isomers exist in the stems of the plant to the extent of about one per cent, the content increasing through the spring and summer and becoming maximal just before the frosts, the old Chinese custom of collecting the plant for medicinal use in the autumn thereby being vindicated.

The Chinese herb containing ephedrine and called *Ma Huang* (yellow astringent) was employed empirically by native physicians for over 5000 years. The Emperor Shen Nung (2760 B.C.) is supposed to have tasted *Ma Huang,* as well as all other drugs in the pharmacopeia, and placed it in the "medium class." The Chinese Dispensatory (Pentsao Kang Mu) written in 1569 by Shih-Cheng Li mentions that the drug is valuable as an antipyretic, diaphoretic, circulatory stimulant and sedative for cough. Ephedrine came to be an ingredient of several favorite native prescriptions. The plant was also widely employed in Russia for many centuries, particularly for respiratory disorders and rheumatism. The Indians and Spaniards of the southwestern United States used ephedrine plants for various medicinal purposes, especially venereal diseases.

An active principle was first isolated from *Ma Huang* by Yamanashi in 1885. Nagai obtained the alkaloid in pure form two years later and named it *ephedrine.* Pharmacological investigation by Japanese workers indicated that the drug was toxic, large doses having been used. Its mydriatic properties were noted by Miura (1887), however, and as early as 1888, Takahashi and Miura concluded that the drug caused dilatation of the pupil through stimulation of the sympathetic nerves. Ephedrine then enjoyed a passing vogue as a mydriatic, several years before the isolation of epinephrine. Japanese scientists continued their investigations of the alkaloid, observed its sympathomimetic properties and employed it in the treatment of asthma.

Interest in ephedrine in Western medicine was created by the investigations of Chen and Schmidt which began in 1923 as a result of a Chinese druggist's assurance that *Ma Huang* was really a potent drug. These workers established the cardiovascular effects of the alkaloid, its similarity to epinephrine and the fact that it could be effectively absorbed from the intestinal tract (Chen and

Schmidt, 1924). Numerous clinical and experimental studies soon followed and the use of ephedrine spread so rapidly that 10 tons of the alkaloid are now consumed yearly. Synthetic ephedrine (racemic) was first prepared in 1927 and marketed under the name *ephetonin.* The details of the interesting history and pharmacognosy of ephedrine may be found in the extensive review by Chen and Schmidt (1930).

Chemistry. Ephedrine differs chemically from epinephrine in two important ways—it lacks the hydroxy groups on the benzene ring and it contains a third carbon atom on the aliphatic chain in the form of a methyl group (Table 21). These two differences account for the many properties of ephedrine which are distinct from those of epinephrine, particularly greater stability and actions on the central nervous system. The discovery of ephedrine stimulated the search for other sympathomimetic amines with three carbon aliphatic chains which would possess advantages over epinephrine, and from this search at least one important therapeutic agent has been obtained, namely, benzedrine.

Inasmuch as ephedrine contains two asymmetric carbon atoms, two sets of stereoisomers, six in all, are possible. The six have been prepared synthetically and they are designated as *l-*, *d-*, and *dl*-ephedrines and *l-*, *d-*, and *dl*-pseudoephedrines. Only two of the six alkaloids are found in the plant, however, these being *l*-ephedrine (the one official in the U.S.P.) and *d*-pseudoephedrine, and these two are more active than the other four isomers. Pseudoephedrine differs from ephedrine in physical properties and somewhat in pharmacological activity. The chemical difference lies in the relation between the -OH on the alpha and $-NHCH_3$ on the beta carbon, the groups being close to each other in ephedrine and removed from each other in pseudoephedrine.

Mechanism of Action. The earlier theories concerning the mode of action of ephedrine have been reviewed at length by Chen and Schmidt (1930). These theories antedate the newer concepts of the mediation of the nerve impulse and thus require revision to conform to the modern knowledge of the mechanisms of action of autonomic drugs. Because of the fact that ephedrine and related sympathomimetic amines resemble epinephrine so closely in their pharmacological properties, it is tempting to assume that their mechanism of action is identical with that of the hormone of the adrenal medulla, that is, that they act directly on autonomic effector cells. In the case of ephedrine, at least, this assumption cannot be so readily accepted because the drug has certain pharmacological properties which are not easily reconciled with the theory of a direct cellular action. Ephedrine differs from epinephrine in not evoking enhanced responses after cocaine or after sympathetic denervation of certain effector organs. Indeed, these two conditions may diminish the activity of ephedrine. Whereas rapidly repeated doses of epinephrine result in no diminution in the responses to the drug, the effects of ephedrine diminish with each successive dose (tachyphylaxie). Furthermore, the vasopressor action of ephedrine is not reversed by ergotoxine as is true for epinephrine, and evidence of a vasodilator component is not obtainable. Also, ephedrine does not exhibit much activity on isolated tissue (Schaumann, 1928; Burn, 1932). Finally, under certain experimental conditions, large doses of ephedrine tend to antagonize or even reverse the actions of epinephrine (Schaumann, 1928; Curtis, 1929; Burn and Tainter, 1931; Thienes and coworkers, 1934).

It is difficult to see how the many differences between the actions of ephedrine and epinephrine can be resolved by a single explanation. Nevertheless, several of them have been interpreted on the basis that ephedrine exerts an inhibiting effect on the enzyme which oxidizes epinephrine. It will be recalled that *amine oxidase* destroys epinephrine but not ephedrine (page 410), and this accounts in part for the greater stability of ephedrine in the body. Also, ephedrine inhibits amine oxidase *in vitro* (Blaschko, Richter and Schlossmann, 1937; Blaschko, 1938; Richter, 1937). Gaddum has advanced the hypothesis that ephedrine acts to inhibit amine oxidase and likens its mechanism of action to that of eserine which inhibits cholinesterase (*see* Gaddum, 1938). Thus, just as eserine protects the acetylcholine released at cholinergic nerve terminals from enzymatic destruction, so ephedrine may protect the epinephrine-like substance (sympathin) released at adrenergic terminals. Under conditions when sympathin is not released, as in denervated structures or in isolated tissue, ephedrine may not exhibit sympathomimetic properties, just as eserine is inactive under comparable circumstances. When small amounts of epinephrine are added, however, the activity of ephedrine is restored, just as the addition of acetylcholine permits eserine to manifest its activity. Indeed, the experiments of Schaumann (1928), Reinitz (1929), Koppanyi and Luckhardt (1931), Burn (1932), Pak and Tang (1933), Gaddum and Kwiatkowski (1938) and others indicate that ephedrine may potentiate the effects of epinephrine under a variety of circumstances and that when the experimental situation is such that ephedrine is inactive, the addition of minute amounts of epinephrine permits ephedrine to exhibit its characteristic actions. That ephedrine potentiates both epinephrine and adrenergic nerve impulses by protecting the hormone or sympathin from enzymatic destruction also receives support from the experiments of Gaddum and Kwiatkowski (1938). These investigators have demonstrated that low concentrations of ephedrine sensitize the isolated perfused rabbit's ear, the cat's nictitating membrane and the frog's heart not only to epinephrine but also to the stimulation of adrenergic nerves. Furthermore, the sympathin released by stimulation of adrenegric nerves was shown (by a sensitive colorimetric method) to be detectable in increased amounts in the perfusion effluent when ephedrine was present during the period of nerve stimulation.

The theory of Gaddum also attempts to elucidate the known facts that large doses of ephedrine antagonize the effects of epinephrine under certain circumstances and that rapidly repeated doses of ephedrine elicit diminishing responses. In explanation, it is assumed that ephedrine combines with the same chemical receptor substances in effector cells with which epinephrine combines, but that the former drug produces no effects when so combined with cells. The receptors thus become blocked by ephedrine so that epinephrine or sympathin cannot affect them. In other words, in high concentrations ephedrine prevents epinephrine, the substance through which it acts, from reaching effector cells.

The hypothesis presented above, in its simplest terms, claims that ephedrine acts as a substrate which combines with amine oxidase, the enzyme in the body which is presumed to destroy epinephrine, and that by successfully competing for the enzyme it protects epinephrine and prolongs its actions. Ephedrine could fill such a rôle in substrate competition because it resembles epinephrine in chemical structure but is more stable. The theory would account for the lack of activity of ephedrine on isolated and denervated structures, for the occasional antagonism between epinephrine and ephedrine and for the decrement with which ephedrine acts when its administration is rapidly repeated. However, many problems remain unsolved and more data are necessary to test the worth of the theory. Little is known concerning amine oxidase, its concentration in different loci in the body and whether it has a physiological function in connection with the organization of the adrenergic nervous system. The experimental results of Richter and Tingey (1939) questioning the ability of amine oxidase to account for the rapid *in vivo* destruction of epinephrine have already been cited (page 410). Indeed, these investigators found that the enzymatic destruction of epinephrine was not inhibited by ephedrine (in the particular concentrations employed). Nevertheless, Gaddum's suggestions are provocative and provide the basis for further experimentation from which many interesting facts may develop.

Pharmacological Actions

Ephedrine is a potent sympathomimetic agent which, in its peripheral actions, produces responses which simulate those obtained by stimulation of adrenergic nerves. Therefore, reference to Table 17 indicates, in a general way, the results to be expected from administration of the drug. Ephedrine raises the blood pressure, stimulates the heart muscle, constricts arterioles, relaxes the smooth muscle of the bronchi and gastro-intestinal tract, dilates the pupil, increases the metabolic rate, etc. In addition, however, it has a potent stimulating action on the central nervous system.

Major Pharmacological Differences Between Ephedrine and Epinephrine. The pharmacodynamic differences of academic interest between ephedrine and epinephrine have been presented under the section on mechanism of action. Certain other differences of therapeutic importance may be summarized here. Ephedrine, due to its stability, can be given by mouth. Furthermore, the duration of action of ephedrine is greater than that ordinarily obtainable with epinephrine. The constrictor effect of ephedrine on arterioles is less marked than that of epinephrine but ephedrine lacks the vasodilator component which in the case of epinephrine accounts for the fall in diastolic pressure and after-congestion. Ephedrine, repeated at too frequent intervals, may fail to exert its characteristic responses. The drug possesses a mydriatic action which makes it of value in ophthalmology. Ephedrine also stimulates the central nervous system, an action which is useful in the treatment of poisoning by central depressants and in the symptomatic therapy of narcolepsy. Finally, ephedrine exerts beneficial effects on the skeletal muscle weakness of myasthenia gravis, an action not shared by epinephrine.

Cardiovascular Actions. The effects on the cardiovascular system seen after oral or parenteral administration of ephedrine are similar to those described for epinephrine, the blood pressure being elevated, cardiac output enhanced and peripheral vessels constricted. The onset of the pressor response is slower, however, and the hypertension is much more sustained. For example, a given dose of epinephrine produces a pressor response which is from 100 to 200 times as intense as that of the same amount (by weight) of ephedrine but the effects of ephedrine persist for from seven to 10 times as long (Table 23). The compensatory bradycardia characteristically observed when epinephrine is injected intravenously in animals is less prominent in the case of ephedrine due to the fact that the hypertension develops more slowly. Even the smallest effective doses of ephedrine are vasopressor, in contradistinction to the vasodilatation caused by minute amounts of epinephrine, and a hypotensive phase does not ensue when the pressor action of ephedrine has subsided. Also, ergotoxine does not reverse the ephedrine-induced hypertension. Ephedrine acts more prominently on the heart than on the peripheral vessels, and its direct myocardial effects are the major factors in the cardiovascular responses. As stated previously, when repeated doses of ephedrine are given at frequent intervals, cardiac stimulation becomes less and less prominent and ultimately depression of the heart may occur. A possible explanation for this has been offered. The phenomenon of cardiac depression has been reviewed at length by Chen and Schmidt (1930). Very large doses of ephedrine may occasionally cause myocardial depression without much evidence of preceding stimulation. This fact enjoins caution in the use of excessive amounts of the alkaloid in patients with cardiovascular disease, and the intravenous use of the drug is not advisable.

The vasoconstrictor action of ephedrine is manifested especially on arterioles, capillaries being only slightly affected. The constriction is not as prominent as that produced by epinephrine, and thus the drug is not serviceable in local anesthetic solutions. The action is more prolonged, however, and topical application of solutions of the drug to mucous membranes results in satisfactory relief of vascular congestion unaccompanied by after-dilatation. Ephedrine acts on the *coronary* arteries in a manner similar to epinephrine, and it is likely that its predominant effect is vasodilatation. Stoland and Ginsberg (1934) found that ephedrine caused a marked and sustained increase in coronary blood flow in the intact dog. The increase was independent of a rise in blood pressure and repeated injections of the drug produced less and less effect on coronary flow. Melville (1933) found that ephedrine, like epinephrine, dilated the coronary arteries sufficiently to overcome the vasoconstriction produced by posterior pituitary extract.

TABLE 23

RELATIVE POTENCY AND DURATION OF PRESSOR ACTIVITY OF EPINEPHRINE CONGENERS *

						ACTIVITY OF EPINEPHRINE = 1	
						Pressor Activity	Duration of Pressor Action
Phenylethylamine	H	H	H	H	H	0.005–0.0125	3–4
Tyramine	OH	H	H	H	H	0.01–0.05	2
Synephrin	OH	H	OH	H	CH_3	0.01–0.04	4
Neo-synephrin	H	OH	OH	H	CH_3	0.2	2
Arterenol	OH	OH	OH	H	H	1.5	2
Epinephrine	OH	OH	OH	H	CH_3	1	1
Benzedrine	H	H	H	CH_3	H	0.002–0.01	5–10
Propadrine	H	H	OH	CH_3	H	0.003–0.017	7
Ephedrine	H	H	OH	CH_3	CH_3	0.005–0.01	7–10
Paredrinol	OH	H	H	CH_3	CH_3	0.033	10

* Modified from Gaddum (1939) and Gunn (1939).

Ephedrine, in addition to causing tachycardia, is capable of disturbing ventricular conduction and producing ventricular rhythms such as extrasystoles and fibrillation. Barbital administered beforehand provides a high degree of protection (Meek and Seevers, 1934). Arrhythmias are more rare after ephedrine, however, than after epinephrine, and it is difficult or impossible, for example, to precipitate ventricular fibrillation by injecting ephedrine in cats anesthetized with chloroform, an almost constant occurrence when epinephrine is employed. Nevertheless, in patients with serious organic heart disease or in persons receiving digitalis, ephedrine apparently can produce untoward disturbances of rhythm (Bloedorn and Dickens, 1928; Chen and Schmidt, 1930; Johnson and Gilbert, 1931; and others). Similar results have been reported in animals receiving digitalis and ephedrine (Seevers and Meek, 1935).

Cardiovascular Responses in Man. The cardiovascular responses in man observed after the administration of ephedrine were first studied by Miller (1925) who noted a rise in blood pressure in 70 of 84 individuals given 50 to 125 mgm by the oral or subcutaneous route. In seven cases, the pressure was unaltered and in six it fell. A bradycardia at the height of the rise in blood pressure was observed in the majority of persons. The hypertension persisted from six to eight hours and varied from a minimal amount to 65 mm of mercury above the control level. Similar results have been reported by many workers (*see* review by Chen and Schmidt, 1930). Subsequent investigators reported variable effects on the pulse rate, acceleration occurring in some subjects, no change or a bradycardia in others. It was also observed early that repeated administration of the drug allowed sustained elevation of the blood pressure for several days.

More elaborate studies of the cardiovascular responses to ephedrine have been made by Starr and collaborators (1937), whose results are listed in Table 22, which compares ephedrine with epinephrine. In six subjects, 50 mgm of ephedrine sulfate were injected subcutaneously and studies made at the height of action of the drug, that is, after 15 to 45 minutes. Although the subjects varied somewhat in their responses, the average results indicate a significant increase in pulse rate, systolic blood pressure, cardiac output and cardiac work. Although the pattern in the main resembles that of epinephrine, peripheral resistance is not decreased nearly so much, the heart is stimulated less, and the diastolic pressure does not fall. The elevated blood pressure is due to increased cardiac output inasmuch as peripheral resistance is diminished, the latter occurring solely as a compensatory mechanism because ephedrine lacks a vasodilator effect on blood vessels. The electrocardiograms of all but one patient showed diminution in the height of the T wave after ephedrine. One case exhibited a biphasic T wave. Changes in the electrocardiogram of subjects receiving ephedrine have been reported by others and have also been noted in animals. Patients with hyperthyroidism and essential hypertension may be more sensitive to ephedrine than normal persons, a phenomenon also observed with epinephrine.

Respiratory Effects. Ephedrine influences respiration in two ways, by dilating the bronchioles through a peripheral sympathomimetic action in a manner similar to epinephrine and by a direct stimulation of the respiratory center. Epinephrine lacks this second mechanism of affecting respiration. Respiratory stimulation from ephedrine is especially prominent when depression due to drugs is present, and thus the alkaloid is useful in the therapy of poisoning by central nervous system depressants. Even in normal subjects Starr and coworkers (1937) found that ephedrine increased respiratory minute volume by about 20 per cent (Table 22). Although experimental observations on laboratory animals seem to indicate that ephedrine is more serviceable against the respiratory depression of certain depressants (morphine) than others (phenobarbital), this difference is not evident clinically and ephedrine is one of the most useful respiratory stimulants. The antispasmodic effect of ephedrine on the bronchial muscles is less prominent but more sustained than that of epinephrine, and thus ephedrine is of value only in milder forms of asthma or in chronic cases when continued medication is needed.

Central Effects. In addition to its action on the respiratory center, ephedrine is a potent central vasomotor stimulant. The drug likewise stimulates the cortex and subcortical centers, actions which account for the insomnia, nervousness, tremor and motor restlessness occurring from overdoses and which provide the basis for the use of the drug in *narcolepsy, cataplexy* and as an *analeptic* in cases of poisoning due to anesthetics or other central depressant drugs. For example, Raginsky and Bourne (1931) found that ephedrine could shorten or interrupt avertin anesthesia in both dogs and man, and a large literature exists showing similar effects in other types of drug depression. Central stimulation produced by ephedrine also involves the spinal cord where it results in heightened spinal reflexes. Whether the efficacy of ephedrine in myasthenia gravis can be explained on the basis of its actions on the cerebrospinal axis is not known. The mechanism of the central stimulation produced by ephedrine is also unknown.

In decapitated dogs, Hinsey, Ranson and Zeiss (1931) observed that ephedrine facilitated the development of an extreme degree of resistance to passive flexion of the limbs. When properly balanced on the hind limbs, the dogs given ephedrine were able to stand and support their body weight for considerable periods of time. The animals were definitely livelier and more active reflexly than controls which were not injected with the drug. Jacobsen and Kennard (1933), employing spinal monkeys, observed that ephedrine caused an increase in the excitability of the spinal reflexes in acute preparations and hastened recovery from acute spinal "shock." In chronic preparations, ephedrine likewise caused an increase in reflex excitability. It is likely that the results of both groups of investigators are due to a direct excitatory effect of ephedrine on the spinal motor centers rather than to changes in blood supply to the spinal cord.

Actions on Smooth Muscles. The actions of ephedrine on the musculature of the blood vessels and bronchi have been discussed. The drug acts on the *iris* to cause mydriasis, an effect not generally observed after epinephrine. Mydriasis occurs both after local application of ephedrine to the conjunctiva and after systemic administration. The reflexes to light and accommodation are not abolished, cycloplegia does not ensue and the intra-ocular pressure is not altered. The drug is not serviceable in the presence of inflammation and is more effective in eyes with light-colored irides. Denervation of the pupil does not sensitize it to the mydriatic action of ephedrine, as it does to epinephrine.

The effect of ephedrine upon the *gastro-intestinal tract* is essentially one of relaxation of the musculature and inhibition of peristalsis (Gruber, 1936). The emptying time of the stomach may be appreciably delayed. Van Liere and associates (1936) observed that the oral administration to normal young adults of 65 mgm of ephedrine 20 minutes before a standard meal increased the emptying time almost twofold.

Although ephedrine acts on the musculature of the urinary bladder in a manner similar to that of epinephrine and adrenergic nerve stimulation, relaxation of the *detrusor* muscle is not prominent following administration of the drug. The tone of the *trigone* and vesical *sphincter,* however, is definitely increased. Vesical sphincter spasm has been observed as a result of the use of ephedrine, and patients receiving full therapeutic doses may complain of difficulty and discomfort in voiding. Urinary retention is particularly prone to occur in males approaching the age of prostatic hypertrophy (Boston, 1928; Balyeat and Rinkel, 1932; Valentine and Fitzgerald, 1935). The increase in vesical sphincter tone caused by ephedrine is the basis for the use of the drug in patients with nocturnal enuresis or dribbling due to poor sphincter tone. The isolated *uterus* is usually stimulated by ephedrine regardless of the response manifested to epinephrine.

Miscellaneous Actions. The effect of ephedrine on *secretions* is not prominent. *Sweating* occurs after ephedrine in man but is not demonstrable in animals. The metabolic effects of ephedrine are similar to those of epinephrine. Thus, the drug causes *hyperglycemia* but the action is not as prominent nor as constant as after epinephrine. The *metabolic rate* is increased in man (Table 22), but the response is not marked. Changes observed in the formed elements of the *blood* after administration of ephedrine are similar to those noted after epinephrine and are due to contraction of the spleen.

Absorption, Fate and Excretion. Ephedrine is adequately and readily absorbed from the intestinal tract, including the rectum. It also enters the circulation rapidly after subcutaneous or intramuscular injection. Parenterally administered ephedrine is more quickly absorbed than epinephrine, probably due to the fact that it lacks marked constrictor effect on capillaries. The fate of ephedrine in the body is unknown. The drug is not destroyed by amine oxidase, the enzyme which oxidizes epinephrine, and the resistance of ephedrine to destruction accounts for its prolonged duration of action. Thorp, Essex and Mann (1933) perfused ephedrine sulfate through heart-lung, heart-lung-limb and heart-lung-liver preparations for three hours and found that the pressor activity of the alkaloid was not diminished. Practically nothing is known concerning the excretion of the drug from the body, except that it is not rapidly eliminated by the kidneys.

Preparations. Both ephedrine and its salts are official and a variety of preparations is available.

Ephedrine, U.S.P. The official ephedrine alkaloid is levorotatory and may be obtained from *Ephedra equisetina* Bunge, *Ephedra sinica* Stapf, and other species of *Ephedra,* or produced *synthetically*. Ephedrine base is an unctuous, almost colorless solid or crystalline material. Even as the base, it is soluble in water to give an alkaline solution, and is also soluble in alcohol and liquid petrolatum, the latter becoming turbid if the ephedrine is not dry. Ephedrine base is available in the anhydrous form for the preparation of solutions in oil. Ephedrine is also marketed in N.N.R. preparations as an *inhalant* solution (one per cent in light liquid petrolatum) for application to the nasal mucous membranes, and as an *ointment* (one per cent). The N.F. contains the following preparations of ephedrine base: *Ephedrine Spray* (one per cent ephedrine and 0.2 per cent methyl salicylate in light liquid petrolatum) and *Compound Spray of Ephedrine* (one per cent ephedrine with camphor, menthol and oil of thyme in light liquid petrolatum).

Ephedrine Hydrochloride, U.S.P., B.P., and Ephedrine Sulfate, U.S.P. These two official salts are fine white, odorless crystals or powders, and are levorotatory. The hydrochloride salt is soluble 1:3 in water, the sulfate salt being freely soluble in water. Aqueous solutions are quite stable and are not decomposed by exposure to light, air or heat. The salts are available in *capsules* or *tablets* for oral use (25, 32, or 48 mgm), in *aqueous solution* (three per cent), in sterile *ampules* for hypodermic injection (25 or 50 mgm per cc) and in *hypodermic tablets* (16 and 32 mgm each). Syrups and nasal jellies are also marketed, and the N.F. contains the following preparations: *Jelly of Ephedrine Sulfate* (one per cent aqueous solution with methyl salicylate, eucalyptol, oil of dwarf pine needles, glycerin and tragacanth) and *Syrup of Ephedrine Sulfate* (containing 16 mgm per four cc dose, in syrup of cherry). The N.N.R. also includes *synthetic racemic ephedrine* (*Racĕphedrine Hydrochloride*), the actions, uses and doses of which are similar to the levorotatory salts.

Doses and Routes of Administration. The *oral route* of administration is preferred when systemic effects are sought. The usual oral dose for adults varies from 15 to 50 mgm, depending on the results desired. When chronic medication is necessary, smaller doses are usually given at three to four hour intervals. Ephedrine is ordinarily prescribed in the form of its salts and can be taken in capsules, tablets or solution. Ephedrine may also be given by *injection,* subcutaneously or intramuscularly, the dose being similar to that employed orally. Absorption from hypodermic sites, however, is not appreciably more rapid than from the intestinal tract. For *topical application* of drops or sprays to mucous membranes, solutions varying in strength from 0.5 to 3.0 per cent are used, in aqueous or oil solution, or the drug may be administered as a jelly or ointment.

For mydriasis, aqueous solutions, at least 3.0 per cent in strength, must be instilled in the conjunctival sac.

Toxic Reactions and Precautions. Most patients receiving sufficiently large doses of ephedrine experience nervousness, insomnia, tremulousness, vertigo, headache, palpitation, sweating and warmth. These symptoms, however, vary considerably in different individuals. Some patients complain of nausea, vomiting and anorexia, and precordial pain has been reported. The difficulty in urination due to vesical sphincter spasm has been mentioned. Cardiac arrhythmias may occur after ephedrine. Side-effects due to the central actions of the drug are adequately and completely counteracted by sedatives such as the barbiturates. The combined use of ephedrine and a barbiturate is sometimes resorted to in patients who are made nervous and sleepless by ephedrine when chronic medication with the latter drug is necessary. Occasionally, a patient may manifest hypersensitivity to the alkaloid and *contact dermatitis* may then occur from the topical application of its solutions.

In using ephedrine, the same precautions and contraindications should be observed as outlined for epinephrine. Special care should be exercised in using the drug in patients with organic heart disease or cardiac decompensation, hyperthyroidism, hypertension and angina pectoris, or in persons receiving digitalis. Chronic intoxication from repeated administration of ephedrine is unknown. Although some measure of tolerance may develop to the drug, addiction does not occur.

Therapeutic Uses

Ephedrine enjoys the same general field of clinical usefulness as does epinephrine, but in addition it can often be employed when epinephrine is not serviceable, due to the fact that ephedrine can be taken orally, has a longer duration of action and possesses therapeutic value as a central nervous system stimulant. Also, ephedrine is of benefit in myasthenia gravis.

Clinical Uses of Cardiovascular Actions. *Spinal Anesthesia.* The prolonged vasopressor action of ephedrine allows the drug to be employed for maintaining the blood pressure during spinal anesthesia. Ephedrine is probably the pressor agent of choice to prevent the hypotension accompanying spinal anesthesia. The fall in pressure is anticipated by the subcutaneous administration of 35 or 50 mgm of ephedrine from 30 to 45 minutes prior to anesthesia. The use of the alkaloid allows spinal anesthesia to be employed in hypertensive or hypotensive patients in whom the procedure might otherwise be contraindicated. Hypotensive subjects are sometimes resistant to the effects of the drug and should therefore be given a test dose to determine whether they are sufficiently responsive to undergo subsequent anesthesia. Ephedrine also improves the respiration, allows a better color of the skin and mucosae and lessens peripheral bleeding (Weinstein and Barron, 1936). If the blood pressure begins to fall during the course of the operation, the dose of ephedrine may be repeated. When it is necessary quickly to combat a continued fall in pressure, 25 mgm of ephedrine may be carefully injected intravenously. If this fails to check the fall, it may be necessary to resort to epinephrine.

Chronic Hypotensive States. Ephedrine offers symptomatic relief to many individuals suffering from chronic hypotensive states, especially those with *postural hypotension.* The syncopal attacks occurring in postural hypotension result from the lack of normal cardio-accelerator and vasoconstrictor responses to the assumption of the erect posture or to exercise, and ephedrine often gives striking relief. Even though the blood pressure is sometimes not markedly affected by medication with ephedrine, the patient often feels better and obtains relief from symptoms. This suggests that the improvement is due in part to central effects of the drug on the brain. Dizziness, for example, may be abolished regardless of whether the blood pressure falls to the same low level when the patient assumes a vertical position. Obviously, when neurological disease such as tabes dorsalis, syringomyelia, etc., underly the disorder, or when neurological damage has already occurred due to prolonged hypotension, the drug can offer no more than symptomatic relief. Occasionally, however, a patient is encountered who may be able to discontinue ephedrine after several months without recurrence of symptoms. The drug is given orally as often as necessary, usually 25 to 50 mgm being taken every two to four hours. The first dose each day is taken one hour before arising (Weis, 1935; Ellis and Haynes, 1936; and others).

Shock. The benefit to be obtained from the use of ephedrine in shock is neither striking nor reliable and the drug may do harm. Indeed, in the later stages of shock, ephedrine is definitely contraindicated. Large doses in particular are likely to prove injurious and myocardial depression and a further fall in blood pressure may ensue (page 588).

Complete Heart Block. Ephedrine has proved of benefit in the symptomatic therapy of complete heart block with syncopal seizures (Stokes-Adams disease). Inasmuch as chronic medication is required, the oral use of ephedrine provides a distinct advantage over the hypodermic injection of epinephrine. The minimal effective dose of ephedrine, usually 15 to 30 mgm three times daily, should be prescribed. Doses larger than necessary may have untoward effects because most patients with this syndrome have serious organic heart disease. Ephedrine accelerates the idioventricular rate and thereby removes the usual cause of the syncopal attacks. As was pointed out under epinephrine, however, it is essential to determine, if possible, the exact etiology of the syncopal seizures because ephedrine is contraindicated when transient runs of ventricular prefibrillation underlie the syndrome.

Allergic Disorders. *Bronchial Asthma.* Ephedrine gives symptomatic relief in bronchial asthma in a manner similar to that described for epinephrine, and the drug occupies a well-defined place in the management of asthmatic attacks. Inasmuch as it can be given orally and has a long duration of action, ephedrine can be used to prevent asthma. Indeed, its prophylactic value is greater than its therapeutic value. In acute severe episodes, epinephrine is the drug of choice because ephedrine is too slow in its onset of action and lacks the antispasmodic potency of the former drug. Mild attacks often yield to ephedrine and the alkaloid may abort seizures when given sufficiently early, or reduce their number and severity when given continuously. The drug seems to be more effective in allergic and reflex nasal cases than in the infectious forms of bronchial asthma. The dose ranges from 20 to 50 mgm for adults, given orally or subcutaneously as the case requires. When continued medication is used, central nervous system sedatives may be necessary to overcome the central effects of ephedrine and permit sleep.

Hay Fever. A large percentage of victims of hay fever obtain some measure of symptomatic relief from ephedrine, and a few individuals may even obtain complete relief. The drug is usually given by mouth, but a supplemental nasal spray may add to the patient's comfort. The points enumerated regarding the dosage and use of ephedrine for asthmatics also apply here. Patients who are undergoing various types of skin tests for sensitivity to specific allergens should not receive ephedrine within twelve hours before such tests because the appearance of positive reactions may be prevented.

Mucosal Congestion. In *acute coryza, vasomotor rhinitis, acute sinusitis, hay fever,* etc., ephedrine affords considerable symptomatic relief from nasal mucosal congestion and is used widely for this purpose among the laity. The long duration of action and the lack of after-congestion and intense white ischemia are distinct advantages of ephedrine over epinephrine. After topical application, the onset of vasoconstriction is rapid (few seconds to a minute) and the action on the mucosal vessels may persist for two hours or more. Whether ephedrine is contraindicated in the presence of acute infection of the nasal passages or accessory nasal sinuses is a disputed question. Some rhinologists deprecate the use of vasoconstrictor drugs and claim that such therapy removes protective hyperemia, lowers local resistance and violates the usual principles of management of acute inflammations. However this may be, no one can seriously doubt the great relief which attends the shrinkage of swollen turbinates, the re-establishment of the patency of the upper respiratory airway and the opening of blocked ostia of accessory nasal sinuses with the resulting promotion of drainage. Finally, the upper respiratory infection which characterizes the common cold is a self-limited disease, as a rule, and until it is definitely proved that topically applied vasoconstrictor agents really do harm, they undoubtedly will continue to be widely used by physicians.

The various preparations available for local application have been described. Jellies, drops or sprays may be employed, and the last two may be in oil or aqueous solution. The concentration may vary from 0.5 to 3.0 per cent. Aqueous mixtures are less irritating when they are prepared with isotonic sodium chloride solution. Nosedrops are most effectively administered when the head is in the lateral position, leaning downward (lateral head-low position) (Parkinson, 1939). The claim has been made that solutions in medicated oils may slow ciliary activity and even injure epithelium. This requires confirmation.

Mydriatic Use. The advantages of ephedrine as a mydriatic are its short duration of action and the absence of cycloplegia and increased intra-ocular pressure. It is thus especially serviceable for visualizing the fundi. A three to five per cent solution usually produces, within 30 minutes to one hour, a satisfactory pupillary dilatation which lasts several hours. Inasmuch as high concentrations of ephedrine may prove irritating, the combination of 0.1 per cent homatropine with weaker solutions of ephedrine may be employed. Pupillary dilatation without cycloplegia may be obtained by such a combination. Ephedrine may fail to exert its mydriatic effect in patients with dark-colored irides, and the drug is often ineffective in the presence of iritis or iridocyclitis.

Antidote for Drug Poisoning. Ephedrine is a useful agent in cases of poisoning by central nervous system depressants such as morphine, barbiturates, etc. It not only stimulates the medullary vasomotor and respiratory centers but it also exerts an analeptic effect on higher cerebral centers and thus tends to lessen the degree of depression. The doses of ephedrine and intervals employed depend upon the severity of the intoxication and the response of the patient. Fifty mgm may be used in adults as an initial dose, given by subcutaneous injection. The results obtained by the repeated administration of ephedrine to a patient severely poisoned by phenobarbital are diagramed in Figure 13.

Narcolepsy. The central stimulation produced by ephedrine finds an almost specific therapeutic use in the treatment of patients with narcolepsy. Ephedrine was introduced in the United States for the symptomatic relief of narcolepsy by Doyle and Daniels in 1930, simultaneously with and independently of workers in both England and Czecho-Slovakia. Ephedrine was known to produce insomnia and to counteract barbiturate anesthesia and these facts suggested its use in narcolepsy, a syndrome characterized by attacks of an irrepressible desire to sleep. The lack of detailed knowledge of the pathogenesis of narcolepsy, as well as of the physiology of normal sleep, makes it impossible to state the exact mechanism by which ephedrine acts in narcolepsy. The dose employed for adults varies from 10 to 50 mgm or more, taken orally three times daily. Small doses are used initially and increased gradually until an optimal amount is found which does not cause unpleasant side-effects. Hypertensive patients often can take the drug without the occurrence of further elevation of the blood pressure, and children tolerate the alkaloid quite well. To insure sound nocturnal sleep, which is often disturbed in narcoleptic patients, the last dose each day is administered not later than five P.M. Some degree of tolerance may develop to ephedrine after prolonged use of the drug. Although ephedrine is not a cure, it affords symptomatic relief from both the narcoleptic and cataplectic attacks which terminate entirely or are reduced in number and intensity. Sound nocturnal sleep without terrifying dreams is restored and hypnagogic hallucinations cease. Ephedrine and benzedrine are the only available sympathomimetic agents effective in this syndrome.

Myasthenia Gravis. The pathological physiology of this disease is discussed elsewhere (page 342). Before the advent of prostigmine, ephedrine represented the most useful agent for the symptomatic therapy of myasthenia gravis. Its value was discovered accidentally by Dr. Harriet Edgeworth, herself a victim of the disease, and she described the results obtained in her own case in 1930. The mechanism of action of ephedrine in increasing skeletal muscle power in myasthenia gravis is unknown. Perhaps the action of ephedrine on the cerebrospinal axis is the basis for the improvement the drug affords, although other central stimulants (except benzedrine) are ineffective. It seems unlikely that the action of ephedrine is concerned with the acetylcholine-cholinesterase system of voluntary muscles. That ephedrine, however, may act peripherally on skeletal muscle is suggested by the interesting observations of Burn (1939), who found that when fatigue occurred due to repeated stimulation of the sciatic nerve in dogs, the injection of ephedrine caused a marked rise in tension of the fatigued muscle for a prolonged period. Also, tyramine was twice as effective as ephedrine and dihydroxyphenylethylamine was twenty times as active. The effect on skeletal muscle of the last two compounds far outlasted their pressor action.

Doses of 10 to 25 mgm may be given two or three times daily; larger amounts aggravate the weakness. Some prefer to give small doses of eight milligrams at regular intervals of two hours throughout the day. The smallest effective amounts should be prescribed so that an extra dose may safely be taken in an emergency. Ephedrine appears to improve motor power of appendicular muscles more than that of muscles innervated by cranial nerves. Although some patients have been restored from complete invalidism to a normal existence by the use of ephedrine alone, the results are rarely as dramatic as those obtained with prostigmine. Ephedrine is more effective when combined with other agents. The combination of prostigmine and ephedrine is probably the most satisfactory of all the drugs of therapeutic value in myasthenia gravis. The results obtained by the use of such drug combinations have been reviewed by Viets and Schwab (1939), Schlezinger (1940), and others (page 386).

Miscellaneous Uses. In some patients with *chronic urticaria,* especially when associated with *angioneurotic edema,* ephedrine may keep the patient symptom-free and initiate periods of remission during which medication may be completely stopped. The drug may also be used to prevent *nitritoid crises,* for which purpose it is given orally in a dose of 50 mgm prior to injection of the arsphenamine. Ephedrine has also been employed to relieve the whoop in milder forms of *whooping cough.* In patients with *obstructive emphysema,* ephedrine may increase the vital capacity over 30 per cent, lower the intrapleural pressure and make breathing easier (Alexander, 1935). Good results are limited to those cases which have an abundant bronchial secretion, that is, emphysema associated with asthma or chronic bronchitis. The musculature of the smaller bronchi in such patients with abundant exudate has been found to be thickened and the mucosa hypertrophic and infected. Ephedrine presumably affords relief by decreasing the tone of the thickened bronchial muscles, thus dilating the airway. In patients with *syncopal reactions* of the vagal or depressor type due to abnormal sensitivity of the carotid sinus, therapy with ephedrine may have some beneficial effect (Weiss and coworkers, 1936). The drug has been successfully used in the treatment of *petit mal* not responding to bromides or phenobarbital. In patients with nocturnal *enuresis,* urgency and frequency of urination or poor vesical sphincter tone, ephedrine may afford symptomatic relief, presumably by increasing the tone of the trigone and internal sphincter (Valentine and Fitzgerald, 1935; Brookfield, 1937; and others). Ephedrine may be combined with belladonna for this purpose.

BENZEDRINE
(AMPHETAMINE)

Benzedrine, phenylisopropylamine, is a sympathomimetic amine which resembles ephedrine in a number of respects but differs from it chiefly in possessing greater ability to stimulate the higher centers, particularly the cortex. The initial investigations of this compound were reported by Piness, Miller and Alles (1930), Hartung and Munch (1931), Alles (1933), Alles and Prinzmetal (1933) and Tainter (1933) and it was noted early that the drug was effective after oral administration and that it had considerable pressor activity.

Piness and coworkers described the prolonged vasopressor response to benzedrine in dogs and found that when administered orally or parenterally to man, the drug caused an increase in blood pressure. Hartung and Munch also observed the pressor response to benzedrine in dogs and compared its potency with the isomeric phenylpropylamines. Alles found that benzedrine possessed about 1/100 to 1/200 the pressor potency of epinephrine but that the cardiovascular response was of longer duration, and that the drug also had bronchodilator, analeptic and respiratory stimulant properties. Alles and Prinzmetal then studied the bronchodilator activity of benzedrine in greater detail. Tainter, in an extensive examination of 44 sympathomimetic amines, observed that the pressor response to benzedrine was diminished by repeated injection of the drug or by cocaine, and that ergotamine did not reverse the rise in blood pressure. The first to employ benzedrine for its local actions on the nasal mucosa was Bertolet (1932) and the drug was accepted in 1933 for inclusion in N.N.R. as a vasoconstrictor agent for local application and inhalation in rhinology.

The marketing of the sulfate salt resulted in a rapid extension of experimental and clinical investigations of benzedrine which added to the information concerning the drug and its therapeutic uses. Unfortunately, newspaper publicity concerning the stimulant actions of benzedrine on the central nervous system led to many abuses, and numerous reports of toxic reactions caution against the lay use of the drug without medical supervision.

Chemistry and Relation of Chemical Structure to Pharmacological Actions. Benzedrine, phenylisopropylamine, is closely allied to phenylethylamine, ephedrine and propadrine in chemical structure. It differs from phenylethylamine only in having a methyl group attached to the beta carbon in the aliphatic chain. It differs from ephedrine only in that the latter has a hydroxy group on the alpha carbon and a methyl group on the amino nitrogen. Benzedrine differs from propadrine in lacking the hydroxy group on the alpha carbon. These relationships are shown in Figure 21.

The sympathomimetic properties of benzedrine reside in the benzene ring linked to an aliphatic chain containing an amino group attached to the second carbon from the ring. The pharmacological differences between benzedrine and epinephrine are due especially to the fact that the former drug possesses a three carbon aliphatic chain and lacks hydroxy groups attached to the benzene ring. The structure of benzedrine confers on it resistance to destruction and consequent effectiveness after oral ingestion and a prolonged duration of action. Its configuration likewise accounts for the marked central stimulation which the drug produces, the analeptic action being related chiefly to the three carbon chain with the amino group attached to the middle carbon and the absence of hydroxy groups on the benzene ring (Jacobsen and coworkers, 1938; Gunn, 1939).

Benzedrine exists in three forms due to the presence of an asymmetric carbon atom, the *d-*, *l-*, and *dl*-benzedrines. The dextrorotatory form appears to be from two to four times more active than the other two isomers, as determined by clinical tests in normal individuals and in patients with narcolepsy, postencephalitic Parkinson's disease and postural hypotension (Prinzmetal and Alles, 1939). The order of decreasing potency is as follows: *d*-benzedrine, *racemic* benzedrine, *l*-benzedrine. This is particularly interesting because in most instances, levorotatory compounds possess considerably more pharmacodynamic activity than the dextro or racemic isomers.

Mechanism of Action. The mechanism of the peripheral sympathomimetic actions of benzedrine is unknown. As in the case of ephedrine, it is tempting to assume that benzedrine simply acts directly on muscle and gland cells innervated by adrenergic nerves, as is true for epinephrine. Certain difficulties, however, stand in the way of such an assumption. Benzedrine differs from epinephrine in that it elicits decreasing responses as its administration is repeated (tachyphylaxis) and does not manifest enhanced activity after cocaine or on denervated structures (Tainter, 1933; Detrick and coworkers, 1937; Pinkston and coworkers, 1939). The drug is resistant to destructive deamination by the amine oxidase which oxidizes epinephrine (Blaschko and coworkers, 1937, 1938; Richter, 1937; Beyer and Skinner, 1940), being more resistant than ephedrine. Sympathomimetic amines having the structure $R \cdot CH_2 \cdot CH \cdot NH_2CH_3$ (such as benzedrine and paredrinol) are stronger inhibitors of amine oxidase than those having the structure $R \cdot CHOH \cdot CH \cdot NH_2CH_3$ (such as ephedrine). The theory of Gaddum concerning the mechanism of action of ephedrine (page 424) may eventually be shown also to apply to benzedrine, but more evidence is required, especially concerning the action of benzedrine on various denervated tissues and the effects of combined administration of benzedrine and epinephrine. In this latter connection, Pinkston and coworkers (1939) have demonstrated that benzedrine markedly potentiates the pressor response to epinephrine, a phenomenon also characteristic of ephedrine. Should Gaddum's theory apply, it would suggest that benzedrine acts through preventing the oxidation of epinephrine by amine oxidase and that the compound also competes with epinephrine for the receptor substance in effector cells.

Benzedrine also differs from epinephrine in lacking a vasodilator component.

Thus, after-dilatation does not occur, hypotension does not characterize the terminal stage of the vasopressor response to benzedrine, and ergotoxine fails to reverse the pressor action of the drug.

The mechanism of the central stimulation produced by benzedrine has not been elucidated, although the chemical basis for this action is fairly well understood. Blaschko (1940) has suggested that the ability of the sympathomimetic amines to act as analeptics *in vivo* can be directly correlated with their ability to inhibit amine oxidase *in vitro*. In line with this suggestion, the observations of Mann and Quastel (1940) are pertinent. These investigators found that the respiration of brain tissue was inhibited by certain amines such as tyramine and isoamylamine, which are oxidized to ammonia and their corresponding aldehydes by amine oxidase, the aldehydes exerting inhibitory effects on brain respiration. The addition of benzedrine increases the consumption of oxygen by the brain by binding amine oxidase so that toxic aldehydes cannot be liberated. On the other hand, benzedrine has no ability to increase the respiration of brain inhibited by anesthetic drugs, or to increase oxygen consumption of normal brain tissue. Therefore, the stimulant effect of the drug on normal and anesthetized brains remains unexplained, and it is doubtful whether the peripheral actions of benzedrine on adrenergic structures can be profitably correlated at the present time with the excitatory effects of benzedrine on the central nervous system.

Pharmacological Actions

Benzedrine shares with epinephrine and ephedrine the ability to stimulate effector organs innervated by adrenergic nerves and therefore reference to Table 17 will indicate in a general way the responses to be expected from administration of the drug. The blood pressure is elevated, peripheral vessels constricted, heart muscle stimulated, bronchial and intestinal muscles relaxed, pupils dilated, etc. In addition, like ephedrine, benzedrine stimulates the cerebrospinal axis, especially the brain stem and cortex.

Actions on the Central Nervous System. Benzedrine has the most potent action on the central nervous system of all the sympathomimetic drugs, and this property is the basis of certain unique therapeutic applications. Alles (1933), in noting that benzedrine caused a lightening of anesthesia in his experimental animals, was apparently the first to comment on the central actions of the drug. Numerous reports have subsequently appeared concerning the stimulant and analeptic properties of benzedrine. Attempts have been made to quantitate the potency of benzedrine as a central stimulant in comparison with other analeptics, especially strychnine, picrotoxin, metrazol, coramine and caffeine. The results vary depending upon the investigator, the species and doses employed, the index of recovery selected and the depressants against which benzedrine is measured (Jacobsen, 1938; Tainter, Whitsell and Dille, 1939; Chakravarti, 1939). There is little question, however, that benzedrine is a potent agent for stimulating the medullary respiratory center, lessening the degree of central depression due to anesthetic and hypnotic drugs, and stimulating the normal cerebrospinal axis. Animals receiving sufficiently large amounts of benzedrine exhibit tremors, restlessness, increased motor activity, agitation and sleeplessness to a degree not observed after ephedrine.

Central Effects in Man. Benzedrine is a potent stimulant of the central nervous system in man. The evidence for this conclusion is obtained from the clinical use of benzedrine in narcolepsy, chronic encephalitis, poisonings, etc. In 10 healthy patients, Reifenstein and Davidoff (1938) found that anesthesia produced by the intravenous injection of 0.5 gram sodium amytal was abolished by 10 to 30 mgm of benzedrine injected intravenously. Numerous studies of the *psychic* effects of benzedrine have been made (Myerson, 1936; Davidoff and Reifenstein, 1937; Nathanson, 1937; Guttmann and Sargant, 1937; Fisher, 1937; Gwynn and Yater, 1937; Bahnsen and coworkers, 1938; Jacobsen, 1939; and others). The responses produced depend upon the mental state and personality of the patient and the dose administered. The main results seen after the oral administration of 10 to 30 mgm of the drug are temporary increase in efficiency, confidence, alertness and initiative, an elevation of mood, euphoria, elation, lessened fatigue, enhanced motor and speech activity, increased ability to concentrate, irritability and sleeplessness. Several observers have reported an increase in mental performance by actual objective measurement (Sargant and Blackburn, 1936; Molitch and Eccles, 1937; Bradley, 1937), but the results of Barmack (1938) seem to indicate an increase in the desire rather than in the ability to do mental work.

The effects of benzedrine are not always as described, and many patients may complain of headache, palpitation, dizziness and vasomotor disturbances, or manifest agitation, delirium, depression or fatigue. Larger doses are always followed by fatigue and mental depression. The reversal of central effects also may follow the continued use of moderate doses. The temporary mental stimulation obtained from benzedrine in normal persons, therefore, is not always salutary, and considerable danger lies in the promiscuous use of the drug. The central effects of benzedrine bear no relation to the cardiovascular responses and are often elicited by doses smaller than those which act on the heart or blood vessels.

Respiratory Actions. Benzedrine, like ephedrine, affects respiration in two ways, by stimulating the medullary respiratory center and by dilating bronchioles. Benzedrine in animals causes a marked increase in the rate and depth of respiration through its central action (Alles, 1933; Detrick and coworkers, 1937, and others). Rapidly repeated doses elicit diminishing responses. In normal man, therapeutic amounts cause few detectable changes in respiratory rate, minute volume or vital capacity (Altschule and Iglauer, 1940). When central depression exists, however, the drug may stimulate respiration, an action which is of value in the treatment of poisoning by anesthetics and hypnotics. Although benzedrine dilates the bronchi, the effect is not marked. Clinical use of this action in asthma does not appear promising.

Cardiovascular Responses. Administered to animals in adequate doses, benzedrine causes a rise in both systolic and diastolic pressures and an increase in cardiac output and work. This is apparently accomplished by a direct action of the drug on the myocardium and a peripheral constriction of arterioles. The pulse changes are variable, but cardiac slowing secondary to carotid sinus reflexes is usually noted at the height of the pressor response. As in the case of ephedrine, repeated doses of benzedrine elicit diminishing responses and a fall in pressure may occur in some instances (Tainter, 1933; Detrick and coworkers, 1937; Pinkston and associates, 1939). The potency of benzedrine in comparison with epinephrine on a weight basis is 1:100 to 1:500 (Tainter, 1933; Alles, 1933; Detrick and coworkers, 1937) (Table 23). The cardiovascular responses of animals to benzedrine are characterized by considerable variability, a feature not noted with ephedrine. Cocaine does not potentiate the pressor response to benzedrine and ergotamine does not produce a reversal (Detrick and associates, 1937).

Effects in Man. Benzedrine also elicits variable cardiovascular responses in man, depending upon the dose and route of administration, the presence or absence of disease, and other factors. Although pressor effects may be obtained in normal persons after the oral administration of as little as 10 mgm of the drug, usually larger amounts are required. Both the systolic and diastolic pressures rise.

but this is not invariable and considerable fluctuation, especially in diastolic pressure, may occur. As in the case of ephedrine, a fall in diastolic pressure is not unusual and the pulse pressure is thereby increased. Paradoxical falls in blood pressure have also been observed and unpredictable increases or decreases in both the systolic and diastolic levels, alone or in combination, may occur. Given *subcutaneously* or *intravenously,* benzedrine is much more constant in its pressor effects. In contrast to epinephrine, therapeutic doses of benzedrine in normal subjects do not increase cardiac output or accelerate the velocity of blood flow (Altschule and Iglauer, 1940).

Myerson and coworkers (1936) observed that the subcutaneous administration of benzedrine in 18 subjects in doses of from nine to 50 mgm caused a gradual rise in systolic pressure over a period of 10 to 85 minutes, the pressure returning to normal in from one and one-half to eight hours. The rise varied from 10 to 64 mm systolic, the elevation in diastolic level being less prominent. The spinal fluid pressure increased by 25 to 40 mm of water concomitantly with the blood pressure rise (Figure 43). Alterations in pulse rate were variable, although slowing occurred in the majority of cases, and extrasystoles occasionally appeared. Oral administration of 40 mgm of benzedrine elicited roughly the same blood pressure responses as did the subcutaneous injection, but the elevation occurred more slowly. Fisher (1937) has reported that 30 to 40 mgm of benzedrine given orally to normal persons increased the systolic pressure from 20 to 30 mm of mercury, and the diastolic from 10 to 20 mm, the maximal changes occurring in about two hours and return to normal levels after four hours. The pulse rate was diminished at the height of the pressor response, but accelerated greatly on slight exertion.

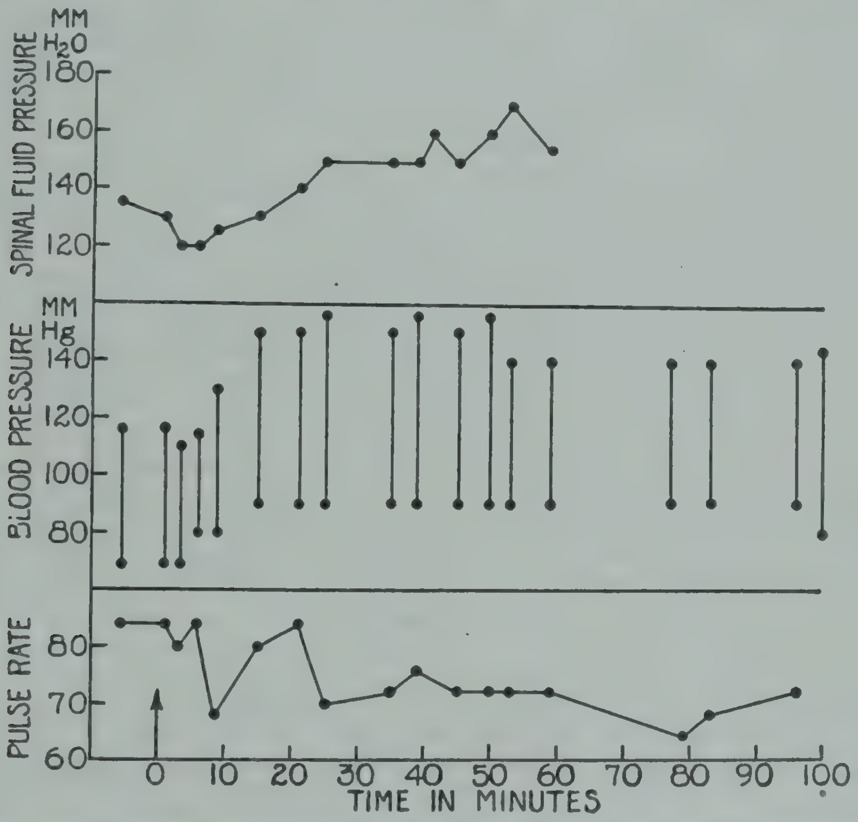

FIGURE 43. *The effect of benzedrine on the blood pressure, heart rate and cerebrospinal fluid pressure in man.*

Normal subject, basal conditions. The arrow indicates the subcutaneous injection of 20 mgm of benzedrine sulfate at zero time. The systolic and diastolic blood pressures began to rise within 10 minutes, reached a plateau at 15 minutes and remained elevated for the duration of the period of observation. The pulse rate decreased. Occasional extrasystoles were noted approximately one hour after the injection. The spinal fluid pressure rose coincident with the elevation of blood pressure. (After Myerson, Loman and Dameshek, 1936. Courtesy of the *American Journal of the Medical Sciences.*)

Anderson and Scott (1936) observed that doses of 10 to 30 mgm of benzedrine given orally caused both increases and decreases in blood pressure and pulse rate, pallor or flushing, palpitation, cardiac pain and extrasystoles. Davidoff and Reifenstein (1937, 1938) also have called attention to the many variations in cardiovascular responses after oral administration of benzedrine. Given intravenously, however, 20 to 30 mgm of the drug usually caused an elevation of 30 to 50 mm in the systolic level and 20 to 30 mm in the diastolic, the maximal elevation occurring within 30 to 60 minutes. Loman and coworkers (1939) reported that 20 to 30 mgm of benzedrine injected intravenously caused increases in blood pressure varying from 30 to 56 mm, and that normal levels were regained in from 40 to 94 minutes. Simultaneous slowing of cardiac rate was noted but arrhythmias did not occur.

Peters and Faulkner (1939) studied the effects in 10 normal subjects and 57 patients with varying types of heart disease of five deep inhalations of benzedrine (inhaler) over a period of two minutes. No significant changes were observed in the pulse rate or blood pressure and only an occasional and unimportant alteration occurred in the electrocardiogram. In only one of 28 patients with angina pectoris did the inhalations appear to precipitate an anginal attack. Dyer (1939) also studied the effects of inhalation of volatile benzedrine in 28 normal persons, 20 inhalations being taken as quickly as possible. The majority showed no change in blood pressure, the highest rise being 10 mm of mercury systolic, the greatest decrease being 15 mm. No consistent alterations in pulse rate occurred. Dyer also investigated the response to 10 to 30 mgm of the sulfate salt taken orally. The majority of individuals given 20 mgm failed to show any change in blood pressure, five of 18 subjects showing a slight elevation (10 to 20 mm) and three responding with a fall (10 mm). With 30 mgm doses, however, nine of 14 subjects exhibited a rise in pressure (10 to 35 mm). Twenty hospitalized patients with varying illnesses and degrees of hypertension were given from 10 to 20 mgm of benzedrine sulfate. Only the larger dose evoked significant changes, 10 of the 20 subjects responding with a rise (10 to 30 mm) and eight subjects manifesting a fall (10 to 25 mm). Obviously, the response to the oral administration of benzedrine is unpredictable. Hypertensive patients tend to show a fall in pressure when in poor health and confined to bed, whereas hypotensive subjects may manifest an increase in blood pressure. Only oral doses of 30 mgm or more cause significant increases in tension.

Arrhythmias of different types may occasionally occur after benzedrine, in normal patients as well as in those with heart disease. These include sinus arrhythmia, extrasystoles of auricular and ventricular origin, paroxysmal tachycardia, marked bradycardia and partial heart block. The electrocardiogram is not greatly altered in the vast majority of cases. Dameshek and coworkers (1938) observed only a slight increase or decrease in the size of the T wave. Precordial pain may occasionally be induced by the drug (Anderson and Scott, 1936).

Benzedrine applied locally to mucous membranes results in shrinkage of congested tissue due to vasoconstriction. This also occurs to a variable extent after oral ingestion, although the result is not as predictable as when ephedrine is employed. Detumescence is not followed by after-dilatation, benzedrine resembling ephedrine and differing from epinephrine in this respect.

Gastro-intestinal Tract. Considerable difference of opinion exists concerning the action of benzedrine on the gastro-intestinal tract. The results of both clinical and animal experimentation are not entirely consistent.

Beyer and Meek (1937) observed roentgenographically that benzedrine reduced by about 30 per cent the initial emptying time of the dog's stomach, but increased by about 15 per cent the final emptying time. No constant effect was detectable on the small intestine regardless of the route of administration of the drug. In a subsequent study (1939), these investigators found that toxic doses did not produce demonstrable effects on the intestine of the intact trained dog; that benzedrine increased the tonus and decreased the amplitude of contraction of the rhythmic pylorus; and that the isolated gut of the dog and rabbit responded to the drug with an increase in amplitude of contraction and decrease in tonus and rate of rhythmic activity. Other *in vitro* investigations indicate that the drug may cause either relaxation or contraction of the excised intestine depending upon the dose employed (Detrick and coworkers, 1937; Boyd, 1938).

In human beings, Meyerson and Ritvo (1936) found that the oral administration of 30 mgm of benzedrine to the average patient overcame spasm of the intestinal tract, thereby greatly facilitating roentgenographic study by making the differential diagnosis between functional spasm and organic defects more certain and giving better visualization of organic lesions. The antispasmodic action reached its height in 15 to 30 minutes, decreased within an hour and gradually disappeared. The drug was also found of value in pylorospasm and spastic colitis. Ritvo (1936) confirmed these results and noted that although the tone of the stomach was decreased by benzedrine, gastric peristalsis was diminished only slightly. The colon became widened, the haustra diminishing in number and prominence, and spastic deformities of the bowel disappeared. Opaque enemas were retained with greater ease by patients receiving benzedrine. Smith and Chamberlin (1937) studied the effect of 20 to 30 mgm of benzedrine given orally or subcutaneously in 28 subjects, including normal individuals and patients having peptic ulcer, spastic colitis or other gastro-intestinal disturbances. They confirmed the findings of the aforementioned workers in that peristalsis in the normal stomach was apparently unaffected and that inhibition may occur in patients with duodenal ulcer. In two patients with gastric atony, gastric tone was increased. The emptying time of the stomach was delayed and the motility of the small intestine diminished. Relaxation of a spastic colon during the administration of a barium enema was also promoted, thus facilitating filling and relieving the patient's discomfort. Occasionally, peristaltic rushes and to-and-fro churning in the small intestine were seen. Van Liere and Sleeth (1938) observed a 20 to 35 per cent decrease in gastric emptying time following the administration of 30 mgm of benzedrine to three normal subjects.

Rosenberg and coworkers (1938) could demonstrate no improvement in 14 of 18 patients with spastic irritable colons who were given benzedrine medication for varying periods of time. In two normal persons, the drug caused pylorospasm and enterospasm and the emptying time of the stomach and small intestine was prolonged. Similar results were obtained in dogs. Beyer and Meek (1939) found that 30 mgm of benzedrine given orally to 10 normal subjects before a test meal caused a decrease of approximately 40 per cent in the time for initial gastric emptying but an increase of about 20 per cent in the time for final emptying, results similar to their animal experiments quoted. Beyer and Meek concluded that the more rapid initial gastric emptying is due to an increase in gastric tonus and intragastric pressure, so that the contents are forced through the pylorus despite the increased tone of that structure. The final delay is due to secondary inhibition of the stomach and possibly to increased pyloric tone. Any value noted for benzedrine in overcoming pylorospasm of moderate degree is thought by these workers to be due to the initial increase in gastric tone overcoming pyloric resistance rather than to a direct inhibitory effect of the drug on pyloric tonus.

In *summary,* it may be stated that the actions of benzedrine on the gastro-intestinal tract cannot be predicted on the basis of the sympathomimetic properties of the drug, and depend on the functional level of activity at the time of drug administration. Apparently the normal stomach is first stimulated so that initial emptying is hastened but later inhibited so that final emptying is delayed. The pylorus usually manifests increased tone. It is possible, however, that paradoxical relaxation may occur in spastic states. The action of benzedrine on the small bowel is uncertain and unpredictable, but the spastic colon at times may be relaxed by the drug, especially when stimuli tending to increase spasm are present, as during the administration of a barium enema. Gastric acidity is not appreciably influenced by benzedrine. Patients receiving the drug may complain of belching, flatulence, anorexia, nausea, abdominal cramps and an increase or decrease in bowel movements. Diarrhea or constipation may also occur.

Pupillary Actions. Benzedrine is a mydriatic when instilled in the conjunctival sac. A one per cent solution causes complete pupillary dilatation in from one-half to one hour, the effect wearing off in less than two hours. The advantages of benzedrine as a mydriatic are that no significant change occurs in intra-ocular pressure, accommodation is not affected and the pupil returns to normal within a short time. Unless benzedrine is repeatedly administered, the light reflex is not lost. Benzedrine and atropine or homatropine employed together in proportionately reduced amounts allow more rapid mydriasis and cycloplegia than is otherwise obtainable and permit recovery to occur much sooner than when the belladonna alkaloids are used alone. For example, an instillation of a five per cent homatropine solution, followed in two or three minutes by a one per cent benzedrine solution, and then in turn by a second instillation of homatropine results in a cycloplegia which reaches a peak in from 50 to 70 minutes and which lasts only a few hours. If a one per cent atropine solution is employed instead of the homatropine, two to four days are required before the patient is again able to read (Myerson and Thau, 1937; Beach and McAdams, 1938; Powell and Hyde, 1938; Mayer, 1939). Myerson and Thau (1937, 1938) noted the interesting fact that benzedrine solution promotes the reappearance of the reaction to light in patients with Argyll-Robertson pupils. The explanation for this is not evident.

Actions on Other Smooth Muscles. The *biliary tract* in human beings is not greatly influenced by benzedrine. Schube and associates (1937, 1939) observed that the drug did not prevent the gall bladder from emptying normally in response to a fat meal given one-half hour after benzedrine. If the drug was administered two hours before the fat meal, however, emptying was prevented. The mechanism of this delayed effect of the drug on the gall·bladder is not clear. At no time was contraction of the viscus observed. Smith and Chamberlin (1937) observed neither stimulation nor inhibition of the gall bladder in their investigations mentioned previously, but they did not study the effect of a fat meal given late after the drug. In cats, Flexner and associates (1938) observed that benzedrine relaxed the gall bladder spasm induced by acetyl-β-methylcholine.

The *detrusor muscle* of the urinary bladder is relaxed by benzedrine and the trigone and sphincter muscles are contracted. Dysuria, frequency and urgency have been reported to occur after the drug. Loman and coworkers (1938), employing intravenous urographic technic, observed that 20 mgm of benzedrine given intravenously caused enlargement of the *kidneys* with an increase in their general visibility, dilatation of the renal pelvis and calyces, relaxation and increase in size of the *ureters,* and marked enlargement of the *urinary bladder* so that it gave the appearance of a cord bladder. These effects are exactly opposite to those noted after acetyl-β-methylcholine.

The *uterus* appears to be contracted by benzedrine. Gunn and coworkers (1939) found that the drug produced contraction of the uterus in all animals, including the non-pregnant cat, benzedrine differing in this respect from epinephrine and resembling ephedrine. Boyd (1938) recorded contraction of the isolated virgin guinea pig uterus after benzedrine.

Metabolic Effects. According to a number of clinical reports, the basal metabolic rate in man does not change appreciably after single doses of benzedrine or after continued medication. In carefully controlled experiments, however, Dill, Johnson and Daly, (1939) studied the metabolic responses to the intramuscular injection of therapeutic doses of epinephrine and benzedrine in man, and found that benzedrine had a definite calorigenic action, smaller than that of epinephrine but more sustained. These investigators noted that epinephrine did not change or slightly increased the proportion of carbohydrate utilized during the period in which the blood sugar and lactate were elevated, acetone bodies in the blood and urine fluctuating within the normal range. Benzedrine, on the other hand, did not modify carbohydrate utilization or the concentration of sugar, lactate or acetone bodies in the blood. The inability of benzedrine to elevate the blood sugar has been verified by several observers. Beyer (1939) reported a small increase in the basal metabolic rate (approximately 15 per cent) in normal human subjects given 30 mgm of benzedrine by mouth. The increase occurred within two and one-half hours and was still noted after nine hours, but the rate returned to normal within 24 hours. In contrast, Altschule and Iglauer (1940) observed that benzedrine given in doses of 10 to 30 mgm orally to 12 normal subjects caused the basal metabolic rate to rise in only two instances, cases in which the increase was attributable to restlessness caused by the drug. Clearly, the rise in basal metabolic rate caused by benzedrine is not constant or significant when compared to that produced by epinephrine.

Miscellaneous Actions. The vascular actions of benzedrine may result in changes in the *skin,* including pallor, flushing, urticaria, dermatographia and paresthesias. Excessive *sweating* may be observed in some patients. Hyperactive *carotid sinus reflexes* are diminished by benzedrine which is thus capable of preventing syncope of the vagal or depressor type (Robinson, 1937, 1938). The *deep reflexes* may be increased by the drug, and the *skeletal muscle* weakness in myasthenia gravis is improved. Changes observed in the formed elements of the *blood* are transient and probably due to the action of benzedrine on the spleen and other blood reservoirs (Pinkston and Pinkston, 1939). Continued administration of the drug does not result in permanent alteration in the blood picture (Schube and coworkers, 1937). The *spinal fluid pressure* rises moderately when benzedrine elevates the blood pressure (Figure 43).

Absorption, Fate and Excretion. *Absorption.* Salts of benzedrine are absorbed adequately and readily from the intestinal tract and from parenteral sites of administration. When benzedrine or its volatile carbonate salt is inhaled in therapeutic amounts for local effects, significant systemic actions are rarely noted.

Fate and Excretion. Benzedrine is quite stable in the body and resists destructive deamination by amine oxidase, this fact accounting for its prolonged duration of action. Benzedrine is even more stable than ephedrine and is excreted slowly by the kidney. In man, excretion begins within three hours after oral administration, and an average of 43 per cent appears in the urine within 48 hours. Obviously, the period of sojourn of the drug in the body outlasts the duration of its action. A large amount of benzedrine apparently is detoxified in the organism. In dogs with liver injury produced by carbon tetrachloride, twice the normal amount of ingested benzedrine is excreted in the urine, suggesting that the liver is the organ which inactivates the compound (Beyer and Skinner, 1940).

Preparations. Benzedrine is available in the form of its sulfate salt for oral administration and for the preparation of solutions, and as the alkaloidal base in inhalers or solution for local use on the mucosa of the upper respiratory tract. The drug is not official, but is included in N.N.R.

Benzedrine, N.N.R. This is the racemic base, a colorless, volatile liquid possessing a strong basic odor and a burning taste. It is soluble in ether, alcohol and liquid petrolatum and is slightly soluble in water. When exposed to air, benzedrine changes to its carbonate salt, which is also volatile. Benzedrine base is available as *Benzedrine Inhaler,* N.N.R., and *Benzedrine Solution,* N.N.R. Each inhaler tube contains, at the time of packing, 0.325 gram of benzedrine, 0.097 gram of oil of lavender and 0.032 gram of menthol. Benzedrine solution is marketed as a one per cent solution in liquid petrolatum perfumed with oil of lavender.

Benzedrine Sulfate (Amphetamine Sulfate), N.N.R. The sulfate salt of benzedrine is not volatile. It is a white odorless powder, freely soluble in water to yield solutions neutral to litmus, and is slightly soluble in alcohol. It is marketed in tablets, each containing 10 mgm of the drug. Benzedrine sulfate is also available as a powder for use in preparing solutions.

Routes of Administration and Doses. *Local Application.* One per cent aqueous solutions of benzedrine sulfate may be instilled in the conjunctival sac for producing dilatation of the pupil. A one per cent solution of benzedrine base in oil may be used in the form of drops or as a spray for shrinking the mucous membranes of the upper respiratory tract. The inhaler is also employed for this purpose. The amount of drug actually inhaled by the use of the benzedrine inhaler has been determined by Simpson and Simon (1937) who found that an average of 21 inhalations were necessary to supply one mgm of the drug. If four inhalations constitute an average treatment, the amount inhaled is only 0.2 mgm. If 20 treatments are employed daily, only four mgm of benzedrine are inhaled. Even if absorption were complete, this would constitute only one-fourth of the single therapeutic dose by the oral route.

Oral. Benzedrine is administered orally as the sulfate salt in tablet form. The average dose for adults varies between 10 and 30 mgm, depending on the result to be obtained. The effects of the drug appear within 30 minutes to one hour. When chronic medication is employed, the single dose is usually 10 mgm, repeated three or four times daily, but larger amounts may be necessary. In order to establish the patient's sensitivity to the drug, five mgm may be given as an initial test dose. Amounts even smaller than this may produce definite cerebral effects.

Subcutaneous. For parenteral injection, the subcutaneous route is preferred. Vascular effects appear within five minutes. The amount administered is determined by the result desired. The usual dose is 10 mgm of the sulfate salt. Intravenous injection is not recommended.

Toxicity. Toxic effects produced by benzedrine are usually extensions of the therapeutic actions of the drug and, as a rule, result from overdosage. Individuals vary in their reactions to benzedrine, and disease also alters susceptibility to the drug. Occasionally, small doses may elicit alarming symptoms due to idiosyncrasy. Most prominent among the toxic effects are the cerebral symptoms. Restlessness, tremors, insomnia, talkativeness and irritability are common. Confusion, assaultiveness, hallucinations, delirium, panic states and suicidal or homicidal tendencies have also been observed, especially in mentally ill patients. Fatigue and depression usually follow the central stimulation. The untoward effects on the gastro-intestinal tract include dry mouth, metallic taste, anorexia, nausea, vomiting and diarrhea. Cardiovascular reactions include chilliness, sweating, palpitation, marked hypertension or hypotension, extrasystoles and other arrhythmias, anginal pain, circulatory collapse and syncope.

Waud (1938) described in detail the effects of prolonged inhalation of benzedrine. In his experiments, the subject breathed through benzedrine inhaler tubes continuously from four to six hours, on eight separate occasions at weekly intervals, probably absorbing many times the usual single therapeutic dose. The chief effects noted were hypertension lasting for four days after each experiment, anorexia and marked loss of weight, mental stimulation including euphoria and increased libido followed by fatigue and depression, diuresis, increased reflexes, and orthostatic hypotension and marked emphysema following the inhalation. Permanent organic changes were not observed and the conclusion was reached that benzedrine has a wide margin of safety in normal persons. Isolated instances of severe reactions to benzedrine have been reported by several investigators. These reactions include convulsions, circulatory collapse and coma in a patient taking 140 mgm with suicidal intent (Apfelberg, 1938), panic in a student three hours after ingesting 30 mgm (Ulrich, 1937) and clonic convulsions and unconsciousness in a patient nine hours after taking 30 mgm (Smith and Chamberlin, 1937). A case of collapse and death possibly due to benzedrine was reported by Smith (1939).

Precautions and Contraindications. Foremost among the precautions to be observed in the employment of benzedrine is to discourage its abuse by the laity as a means of overcoming sleepiness or providing increased energy and alertness.

The Council has voiced the following warning in regard to this abuse (*see* N.N.R., 1940): "Its use is not recommended in the treatment of sleepiness and fatigue in normal individuals because of the possible danger of pressor effects from continued use, because of the dangers of eliminating the warning signal of sleepiness in individuals who are overdoing, because of the possibility of habit formation or addiction from such use and because cases of collapse have ensued when the drug has been used for this purpose. Its use is not recommended for developing a sense of increased energy or capacity for work, or a feeling of exhilaration or as a 'pick-me-up' in individuals other than those under the strict supervision of the physician."

Contraindications to the use of benzedrine are similar to those outlined for ephedrine and epinephrine, and include hypertension, advanced arteriosclerosis, coronary artery disease, states of mental excitement, agitated depression, hyperthyroidism and idiosyncrasy to the drug. Benzedrine should be used with caution in patients with anorexia, insomnia, vasomotor instability, asthenia, psychopathic personalities and history of homicidal or suicidal tendencies.

Habituation to benzedrine may occur in certain patients, and is somewhat similar to the habit formation produced by caffeine and nicotine, but *addiction* in the strict sense of the word is unknown. Several investigators reported an increased tolerance to the drug after continued use, but the majority of patients show no significant change in susceptibility to benzedrine during the course of chronic medication. Bloomberg (1940) reported three cases of narcolepsy in which large doses of benzedrine sulfate (70 mgm or more) were given daily for over two years without any evidence of addiction, habit formation, or deviation from the normal detectable by clinical or laboratory examination.

Therapeutic Uses

In regard to its peripheral sympathomimetic actions, benzedrine has the same general field of usefulness as have epinephrine and ephedrine. Because of its weak bronchodilator activity the drug does not seem to be of value in asthma. It shares with ephedrine the ability to benefit patients with narcolepsy and myasthenia gravis, but in addition it is of value in the symptomatic therapy of certain nervous and mental diseases.

Therapeutic Applications of the Central Actions. *Narcolepsy.* Benzedrine has been found of definite value in the symptomatic therapy of narcolepsy. Prinzmetal and Bloomberg (1935) were the first to record this use of the drug, and several reports have appeared since then (Ulrich, Trapp and Vidgoff, 1936; Davidoff, 1936; Ulrich, 1937; Nathanson, 1937; Solomon and coworkers, 1937; and others). Nearly 100 per cent of narcoleptic patients are completely relieved by benzedrine of attacks of sleep, and cataplexy is greatly improved. Bloomberg (1937) reported a series of 35 cases in which he obtained highly satisfactory results. Benzedrine has proved effective in cases in which ephedrine in large doses failed to give relief. Continued medication over prolonged periods does not seem to result in decreased effectiveness. The dose varies from 10 to 30 mgm, taken orally one to three times daily. The last dose should be given in the afternoon in order not to interfere with nocturnal sleep.

Postencephalitic Parkinsonism. Benzedrine is a valuable adjuvant to the belladonna alkaloids in the symptomatic therapy of postencephalitic parkinsonism. Solomon and Prinzmetal (1936) were the first to employ benzedrine in chronic encephalitis and later (1937) they described their results in a series of 18 patients in which the drug proved beneficial. Since then numerous similar reports have appeared (Davidoff, 1936; Bloomberg, 1937; Matthews, 1938; Davis and Stewart, 1938; Finkelman and Shapiro, 1937; and others). Although some patients are benefited by benzedrine alone, the drug is most beneficial when used with the belladonna alkaloids. In conjunction with atropine, scopolamine or stramonium, benzedrine allows a better sleep cycle, increased energy, subjective improvement in muscle strength and rigidity, a feeling of increased energy, and relief from oculogyric crises. About 85 per cent of patients manifest improvement after benzedrine therapy, and a higher percentage obtain relief from oculogyric crises, for which the drug appears to be almost specific, the attacks being reduced in number and severity or disappearing. Arteriosclerotic parkinsonism is rarely aided by benzedrine and patients with psychotic states accompanying the syndrome are not always favorably affected (Reznikoff, 1939; Reifenstein and Davidoff, 1939). Best results are noted when the disease is postencephalitic in origin and when organic defects and personality changes are minimal. Subjective improvement is greater than objective decrease in tremor and rigidity. The dose employed varies from 10 to 100 mgm or more daily, taken in divided portions.

Alcoholism. In cases of chronic alcoholic addiction, benzedrine occasionally proves of benefit in assisting patients to abstain from alcohol. Fourteen of the 21 cases reported by Bloomberg (1939) appeared to be helped by benzedrine medication. The drug has also been employed as a stimulant in acute alcoholic stupor and may shorten the period of recovery from intoxication. Reifenstein and Davidoff (1940) recorded that nearly all of their patients with acute psychosis due to alcoholism showed accelerated recovery in response to benzedrine, the best results being obtained in cases of recent origin. Mild states of depression following drinking debauches were also benefited. Unsatisfactory results were obtained in chronic alcoholic addiction without psychosis. More experience is required before the indications for and dangers of the use of benzedrine in alcoholism can be evaluated.

Psychogenic Disorders. Benzedrine has been employed in a variety of mental diseases and a large and controversial literature is accumulating concerning its value. It has been used in mild mental disorders such as mood disturbances, chronic nervous exhaustion and psychoneuroses, as well as in major psychoses such as dementia praecox and the depressed form of manic depressive psychosis. The immediate results are quite good in cases of depression and chronic exhaustion and in some instances improvement may be spectacular. The results are not striking in psychoneuroses, and anxiety states may be aggravated. Patients with involutional melancholia do not respond well. Some evidence exists that benzedrine accelerates improvement in patients with the depressed type of manic depressive psychosis and also in certain patients with dementia praecox (Reifenstein and Davidoff, 1939). Wider investigations are required before the value and dangers of benzedrine in psychogenic disorders will be known. Whether it is safe and logical continuously to stimulate individuals with mental disturbances is unknown, and the indiscriminate use of benzedrine in patients with psychic disorders cannot be too severely criticized. (*See* Wilbur and associates, 1937; Nathanson, 1937; Schube and associates, 1937; Solomon and coworkers, 1937; and the review by Reifenstein and Davidoff, 1939.)

Drug Intoxication. Benzedrine has not received extensive trial as an analeptic in cases of poisoning by central nervous system depressants. Although it is capable of lessening the degree of depression produced by anesthetics and hypnotics, benzedrine lacks the potent respiratory stimulant action of caffeine and ephedrine, and thus cannot be relied upon alone. In conjunction with other measures, however, it may prove useful in poisoning by depressant drugs. Boyd (1940) has reported on the use of benzedrine to shorten the period of postoperative unconsciousness following avertin anesthesia in children.

Therapeutic Application of the Cardiovascular Actions. *Local Vasoconstriction.* Benzedrine in the form of the inhaler or solution in oil serves the same purpose as does ephedrine in the treatment of congestion of the upper respiratory mucosa. It is thus widely employed in *hay fever, acute coryza, acute sinusitis, vasomotor rhinitis,* etc.

Orthostatic Hypotension. Benzedrine has received therapeutic trial in orthostatic hypotension where the results appear to be as good as those obtainable with ephedrine. The dose may vary from 50 to 150 mgm daily, given orally in divided portions, the first dose of 25 mgm to be taken one-half hour before arising. Smaller amounts are taken during the day at such intervals as may be necessary to prevent symptoms (*see* Davis and Shumway-Davis, 1937; Korns and Randall, 1937, 1938).

Miscellaneous Uses. Benzedrine is useful in ophthalmological work as a *mydriatic,* for which purpose a one per cent aqueous solution is employed. The advantages of benzedrine and the technic of combining it with the belladonna alkaloids have been described. In patients with *syncope* due to abnormal carotid sinus reflexes, benzedrine decreases the number and severity of attacks (Robinson, 1937, 1938). In *myasthenia gravis,* Thorner and coworkers (1937) found benzedrine advantageous in three of five cases. The mechanism of action of benzedrine is increasing skeletal muscle power in myasthenia gravis is unknown. It probably is identical with that of ephedrine. In *persistent hiccough,* the administration of benzedrine has been reported to check the attacks (Shaine, 1938; Hanelin, 1939). The mechanism of action is not clear. The equivocal *antispasmodic action* of benzedrine on the gastro-intestinal tract has been described. Although the drug may occasionally be beneficial to patients with spastic colitis and may prove useful in roentgenological diagnosis, it lacks the general antispasmodic usefulness of the belladonna alkaloids and their synthetic substitutes. Benzedrine has also been reported to be beneficial in the treatment of *enuresis* in children (Molitch and Poliakoff, 1937) and in *migraine* (Nathanson, 1937). In *epilepsy,* benzedrine is valuable as an adjuvant to phenobarbital, correcting the ataxia and drowsiness produced by the sedative and allowing sufficient amounts of phenobarbital to be employed to control convulsive seizures (Cohen and coworkers, 1940; Ebaugh, 1940; and others).

NEO-SYNEPHRIN

Neo-synephrin is a synthetic, optically active sympathomimetic amine which differs from epinephrine chemically only in that it has one rather than two hydroxy groups on the benzene ring. The hydroxy group is placed in the position meta to the aliphatic side chain (Table 21). Barger and Dale (1910) studied the pharmacological actions of monohydroxy benzene sympathomimetic amines and concluded that meta- and para-hydroxy compounds were equally effective. It was later determined, however, that in the case of monohydroxy derivatives the meta position afforded optimal activity and neo-synephrin replaced an older preparation, *synephrin,* in which the hydroxy was in the para position. In addition, synephrin was a racemic compound and this also reduced its activity.

Pharmacological Actions. The pharmacological actions of neo-synephrin are similar to those of epinephrine. Thus the compound raises the blood pressure by peripheral vasoconstriction and cardiac stimulation. The effect on the heart is less than that of epinephrine and compensatory reflexes (or possibly a direct depression of the S-A node [Keys and Violante, 1940]) slow the heart rate to below normal. Accompanying the bradycardia are an increase in heart size and stroke volume (Keys and Violante, 1940). Cardiac arrhythmias are much less likely to occur than after epinephrine. In contrast to epinephrine, the incidence of untoward reactions from neo-synephrin, such as anxiety, tremor, nervousness, and headache, is low. Lastly, neo-synephrin is much more stable and produces more lasting responses than does epinephrine. After intravenous administration of the compound, the blood pressure remains elevated for approximately 15 minutes, and after subcutaneous or intramuscular injection, one hour to two hours or more. The stability of neo-synephrin allows the drug to be taken orally. After administration of neo-synephrin by mouth, bronchodilatation as well as cardiovascular responses can be observed.

Routes of Administration and Dosage. Neo-synephrin can be given intravenously, intramuscularly, subcutaneously or orally. The intravenous dose is 0.5 mgm; the subcutaneous or intramuscular, approximately five mgm. Adequate pressor effects are obtained after the oral administration of 20 to 50 mgm. For topical application to mucous membranes, a solution of 0.25 per cent is usually employed and for combination with local anesthetics a concentration of 1:5000 is sufficient.

Preparations. *Neo-Synephrin Hydrochloride,* N.N.R., is a white crystalline powder readily soluble in water. It is marketed for topical application as a 0.25 or 1.0 per cent aqueous solution with 0.8 per cent sodium chloride and 0.1 per cent sodium benzoate; for parenteral administration, as a 1.0 per cent sterile isotonic solution. It is also dispensed in a jelly base in 0.5 per cent strength and as a 0.25 per cent emulsion in mineral oil containing camphor, menthol and oil of thyme. Neo-synephrin is stable and resists decomposition by boiling, exposure to light and air, and contact with alkaline solutions.

Therapeutic Uses. Neo-synephrin is extensively employed for *topical application* to nasal mucous membranes for the symptomatic relief of *sinusitis, vasomotor rhinitis* or *hay fever.* It is a suitable agent for *sustaining the blood pressure* during *spinal anesthesia,* being superior to ephedrine in that it does not affect the central nervous system and does not lose its efficacy as a pressor agent upon repeated administration. For this purpose, five mgm may be injected subcutaneously and repeated if necessary (Bittrich, 1939; Brunner and Takats, 1939; Lorhan and Lalich, 1940). It is also employed in a concentration of approximately 1:5000 in solutions of local anesthetics as a *vasoconstrictor agent.* Capaccio and Donald (1938) report an interesting case of *orthostatic hypotension* in which neo-synephrin afforded complete symptomatic relief after ephedrine and benzedrine had proved ineffective. The dose initially employed was 50 mgm by mouth every two hours, but this was soon reduced to 20 mgm, taken three times during the morning.

PROPADRINE

Propadrine is a sympathomimetic amine with actions similar to those of ephedrine. It differs chemically from ephedrine only in that it lacks a methyl group on the amino nitrogen. Its chemical structure is presented in Table 21. The compound was first investigated by Chen and associates (1929) in connection with a series of sympathomimetic amines chemically related to ephedrine. They observed that it had a somewhat greater pressor activity than ephedrine. Clinical reports on the drug reveal that it is less likely than ephedrine and benzedrine to cause central stimulation.

Propadrine Hydrochloride, N.N.R., is a white, crystalline, water-soluble powder. It is marketed in capsules containing 25 or 50 mgm, as a *nasal jelly* containing 0.66 per cent of the drug, and in *aqueous solution* (one and three per cent). The therapeutic indications for propadrine are essentially the same as those for ephedrine, and it may be employed in approximately the same dosage.

KEPHRINE

Kephrine is a sympathomimetic amine which differs from epinephrine in that it has a keto rather than a hydroxy group on the aliphatic side-chain. Its structure is presented in Table 21. Kephrine was studied early in the course of investigations of compounds chemically related to epinephrine and was included in the series investigated by Barger and Dale (1910). At that time it was noted that the keto derivative was less active than epinephrine but that its action was more sustained.

Kephrine Hydrochloride, N.N.R., is a white, water-soluble, crystalline powder. It is employed in therapeutics only for its local action as a hemostatic. It is marketed in *powder form* (diluted to five per cent concentration with tricalcium phosphate), in *rectal suppositories* (containing three parts of kephrine hydrochloride and one part of extract of belladonna in 96 parts of base), and in *impregnated bandage or gauze* (3000 square centimeters being impregnated with one gram of kephrine hydrochloride).

PAREDRINE

Paredrine is a sympathomimetic amine which was first synthesized and patented in Germany in 1913. The compound excited little attention at that time and was not reinvestigated until Alles (1933) studied the pharmacological actions of a series of sympathomimetic amines of which paredrine was one. Shortly thereafter, the compound became commercially available and soon there followed a series of publications on its effects in man and its clinical applicability.

Chemistry. The chemical structure of paredrine and its relation to other sympathomimetic agents are shown in Table 21. The drug is closely related to tyramine, differing only in that it possesses one more carbon atom on the aliphatic chain. It closely resembles benzedrine except that it possesses a hydroxy group in the para position in the benzene ring. These slight changes impart to the compound distinct actions which have therapeutic application.

Pharmacological Actions. Paredrine may be classified as a sympathomimetic amine. It is more stable than epinephrine and practically devoid of actions on the central nervous system. It promises to be of definite value as a mydriatic, is useful as a vasopressor agent when effects on the central nervous system are not desired, but seemingly its actions on the bronchi and gastro-intestinal tract are not sufficiently pronounced to be useful clinically.

Cardiovascular System. Paredrine has a pronounced pressor action. This is evident from experiments both on animals and human beings. Alles (1933) observed that after intravenous injection in anesthetized dogs, the compound was approximately $\frac{1}{50}$ to $\frac{1}{100}$ as active as epinephrine, but had a much more sustained pressor effect. In man, paredrine raises the blood pressure after oral, subcutaneous or intravenous administration, equipressor doses by these three different routes being approximately 20 to 40 mgm, 10 to 20 mgm, and five to 10 mgm, respectively (Abbott and Henry, 1937; Loman, Rinkel and Myerson, 1939). After oral or subcutaneous administration the pressor effect lasts from 90 to 120 minutes. The duration of the response to intravenous injection is about 20 to 30 minutes. Both the systolic and diastolic pressures are elevated, the former sometimes as much as 75 or 100 mm of mercury after the doses cited.

The rise in blood pressure apparently results from both myocardial stimulation and peripheral vasoconstriction. In isolated heart-lung preparations, paredrine accelerates the heart rate, decreases the systolic, diastolic and stroke volumes and increases cardiac output (Crismon and Tainter, 1938). In man, the drug produces modifications of the ventricular complex of the electrocardiogram characteristic of those seen after epinephrine, prevents or abolishes cardiac standstill produced by pressure on the carotid sinus, increases the rhythmicity of the ventricle in heart block (Nathanson, 1939), and supports the blood pressure during spinal anesthesia (Iglauer and Altschule, 1940). Although at the height of the pressor response from paredrine the heart rate is usually slowed, this is due to compensatory circulatory reflexes, and the administration of moderate doses of atropine abolishes the bradycardia (Iglauer and Altschule, 1940). Although many investigators have failed to notice cardiac irregularities resulting from paredrine, Abbott and Henry (1937) reported occasional instances of extrasystoles and persistent coupling.

Paredrine presents some interesting anomalies in its actions on blood vessels. The drug does not cause vasoconstriction when injected intradermally nor does it prolong the duration of action of local anesthetics. After systemic administration of the compound, skin temperature does not fall and indeed the patient may appear flushed. Nevertheless, it seems that vasoconstriction plays a prominent rôle in the pressor action of the drug, possibly the vessels of the splanchnic area responding more markedly than those of the surface. However, in accounting for the pressor effects of paredrinol and paredrine, Stead and Kunkel (1939) believe that the drugs may act on the venous side of the circulatory tree and that this may account largely for the pressor effect (*see* page 452). When the drug is applied to the normal nasal mucous membrane, blanching occurs from exposure to a 0.25 per cent solution and a strength of 1.0 per cent is adequate to shrink congested mucosae (Abbott and Henry, 1937).

Respiratory Tract. Alles (1933) reported that paredrine is effective in dilating bronchi whose musculature exhibited natural or induced tone. However, the drug is clinically ineffective in relieving attacks of bronchial asthma which readily respond to epinephrine (Abbott and Henry, 1937).

Eye. Paredrine, from the reports thus far available, is the most effective of the sympathomimetic amines in regard to mydriatic action and probably more closely approaches the ideal mydriatic than does any other compound. A one per cent solution produces complete dilatation of the pupil within 45 minutes and the effect lasts two hours. A three per cent solution produces complete dilatation within 30 minutes, the effect lasting approximately three hours (Powell and Hyde, 1938; Mayer, 1939). There is little action on accommodation and no significant change in intra-ocular tension. A combination of atropine or homatropine with paredrine causes both mydriasis and cycloplegia. The administration of one drop of a one per cent atropine solution or four per cent homatropine solution followed in three minutes by one drop of a one per cent paredrine solution results within 60 minutes in maximum mydriasis and cycloplegia. Following the homatropine-paredrine combination, effects begin to subside within four to five hours; newsprint can be read within eight hours; and the patient can resume normal use of the eyes within 18 hours. With the atropine-paredrine combination, normal function is restored after three days, but this is in contrast to the 10 to 14 days required when atropine alone is used to produce a comparable loss of accommodation. There is said to be no increase in intra-ocular tension associated with the use of paredrine combined with belladonna alkaloids (Tassman, 1938).

Central Nervous System. Paredrine apparently causes no stimulation of the central nervous system. In a comparative study of the central actions of a group of sympathomimetic compounds, Jacobsen (1938) concluded that only those drugs possessing a three carbon atom aliphatic chain linked to a benzene ring were central stimulants. With the introduction of hydroxy groups into the benzene ring, the property of central excitation was lost. This would account for the marked analeptic effects of benzedrine and the absence of this action in paredrine. All reports on the clinical use of paredrine note the absence of central stimulation.

Untoward Reactions. Paredrine causes few untoward reactions. In a series of 574 injections, Abbott and Henry (1937) record only three instances of toxic responses, these occurring after unusually large doses. The patients complained of intense headache, nausea and vomiting. The effects subsided within a few hours.

Absorption, Fate and Excretion. Paredrine is absorbed in an active form from the gastro-intestinal tract and parenteral sites of administration. The respective durations of activity for different routes of administration have been discussed. Seemingly the drug causes little local vasoconstriction. Thus, after subcutaneous injection paredrine gains rapid access to the circulation and causes a marked pressor response. Presumably the drug is inactivated by the tissues but specific information on its fate and excretion is lacking.

Preparations. Paredrine is not an official drug nor is it described in N.N.R. It is marketed as an ophthalmic solution containing one per cent paredrine hydrobromide and two per cent boric acid in distilled water. Paredrine salts may also be obtained in powder form for systemic administration.

Therapeutic Uses. Paredrine has received a fairly extensive trial in *ophthalmology*. It is a useful mydriatic when employed alone, and in combination with small amounts of atropine or homatropine it is valuable for the production of cycloplegia of brief duration. The drug is administered as outlined above and has the distinct advantages that it produces no irritation or increase in intra-ocular tension and that its effects, although maximal, are brief in duration. Altschule and Gilman (1939) reported on the use of paredrine hydrobromide in supporting the blood pressure during *spinal anesthesia*. Good pressor effects were obtained with 10 or 20 mgm intramuscularly, five or 10 mgm intravenously, or both. No untoward reactions were observed. Nathanson (1939) reported on the use of the drug in *Adams-Stokes disease* and cites one instance in which the patient was relieved of syncopal attacks for two months by the oral administration of paredrine hydrobromide in a dose of 60 mgm three times daily. Paredrine will probably receive more extensive clinical trial because its sustained action and lack of central effects make it a desirable agent in the treatment of certain circulatory disturbances.

PAREDRINOL

Paredrinol is a sympathomimetic amine which differs chemically from paredrine only in that it possesses a methyl group on the amino nitrogen. Its structure is presented in Table 21. Paredrinol was introduced in Germany in 1937 under the trade-name "veritol" and since then has been rather extensively investigated and used clinically in that country. The drug is available in the United States for experimental purposes, but has not been generally marketed.

Pharmacological Actions. The pharmacological actions of paredrinol are essentially similar to those of paredrine. The drug is a relatively stable vasopressor agent which is active after oral or parenteral administration. It has little or no stimulating action on the central nervous system, does not affect metabolic functions, and possesses no outstanding pharmacological properties except those manifested on the circulation. It is probably slightly less potent than paredrine.

Although the mechanisms of action of paredrine and paredrinol are probably the same, attention has been directed to the effects of paredrinol on the venous circulation. This is because Rein (1937), who first investigated the actions of the compound in experimental animals, noted that it produced a marked rise in venous pressure before the arterial pressure was affected. Rein failed to observe a decrease of the blood flow in the extremities and therefore attributed the pressor action to an intense discharge of blood from the splanchnic venous reservoirs. On the other hand, Heymans and Bayless (1937) present a much more orthodox viewpoint as to the mechanism of the pressor action, and on the basis of animal experiments conclude that the drug causes slight peripheral vasoconstriction and pronounced splanchnic vasoconstriction. Reis (1940) also supports the view that arteriolar rather than venous constriction is the basic mechanism of the pressor action.

Stead and Kunkel (1939) investigated the mechanism of arterial hypertension produced by paredrinol in normal human subjects. The drug caused a rise in both arterial and venous pressure but no change occurred in the blood flow of the foot, forearm or calf. Furthermore, intracutaneous injection of the drug did not cause localized vasoconstriction. However, Stead and Kunkel reasoned that increased peripheral resistance did occur for in spite of the greatly increased arterial pressure, blood flow through the tissues and cardiac output remained unchanged. They postulated two possible mechanisms of action: (1) primary constriction of certain portions of the minute vessels which regulate peripheral resistance, and (2) primary constriction of veins and emptying of the vascular reservoirs, causing an increased venous return to the heart and a redistribution of the blood in the arterial and venous portions of the circulation. In support of the latter mechanism of action they observed that if sodium nitrite is administered to individuals whose blood pressure was elevated by paredrinol, the pressure fell to normal only when the subject was in the upright position in which instance the combined actions of sodium nitrite and the upright position result in venous pooling of blood (page 556). When the subject reassumed a horizontal position, the blood pressure again rose to hypertensive levels. Stead and Kunkel reasoned that if the primary pressor effect of paredrinol is due to its actions on the venous circulation, which temporarily would result in an increased venous return and cardiac output, one could account for the peripheral vasoconstriction as that which would occur reflexly in regulating blood flow to a rate commensurate with metabolic demands.

In a more extensive study on the antagonistic actions of paredrinol and nitrites, Stead, Kunkel and Weiss (1939) observed that in many individuals paredrinol prevented the syncope which can be induced by the administration of sodium nitrite to patients in the upright position (page 556). They believe that paredrinol would be a useful drug in the treatment of circulatory collapse caused by the pooling of blood in a dilated venous system, but caution against its use in shock resulting primarily from a loss of fluid from the blood stream (page 586).

The fact that paredrine as well as paredrinol causes venous constriction and an increase in venous pressure in man is confirmed by Iglauer and Altschule (1940). These investigators attribute venous constriction to local stimulation by the drug but they do not believe that venous constriction is a factor in the production of arterial hypertension.

Therapeutic Uses. Paredrinol has been employed for the treatment of a variety of circulatory disturbances but has not received extensive clinical trial in the United States.

CHAPTER 25

AUTONOMIC BLOCKING AGENTS

I. DRUGS INHIBITING STRUCTURES INNERVATED BY POSTGANGLIONIC CHOLINERGIC NERVES

ATROPINE, SCOPOLAMINE AND RELATED SYNTHETIC DRUGS

Historical. The drugs which inhibit structures innervated by postganglionic cholinergic nerves comprise the alkaloids of the belladonna plants. The two most important of these alkaloids are *atropine* and *scopolamine.*

Galenical preparations of belladonna have been employed in medicine for many centuries and were known to the ancient Hindus. The professional poisoners of the Middle Ages often employed the deadly nightshade plant to produce a type of intoxication which was often prolonged and obscure. This prompted Linné to name this shrub *Atropa belladonna,* after Atropos, the oldest of the Three Fates who severs the thread of life. The word "belladonna" itself is a reminder of the antiquity of these medicines in that it signifies "beautiful lady," the women of long ago being wont to instill a decoction of belladonna in their eyes to produce dilated pupils, a sign of comeliness. The resulting disturbance of vision evidently was a small price to pay for beauty. The mydriatic action of belladonna, so widely used today, was thus well understood hundreds of years before the invention of the retinoscope.

Accurate study of the actions of the belladonna drugs dates from the isolation of the pure alkaloids. Atropine was isolated by Mein in 1831 but it was not until the early part of the present century that pure samples of scopolamine became available. The inhibition by atropine of the cardiac effects of vagal stimulation was demonstrated by Bezold and Bloebaum (1867) and the prevention of salivary stimulation upon excitation of the chorda tympani was shown by Heidenhain five years later. These pioneer and fundamental observations were quickly followed by numerous others and today there exists as secure a body of experimental and clinical information on the actions of the belladonna alkaloids as is available for any other drug group.

Sources and Members. The belladonna drugs are widely distributed in nature, especially in the Solanaceae plants. *Atropa belladonna,* the Deadly Nightshade, yields mainly the alkaloids *atropine* and *hyoscyamine.* The same is true of *Datura stramonium,* known as Jamestown or Jimson weed, stink weed, thornapple and devil's apple. The alkaloid *scopolamine* (hyoscine) is found chiefly in the shrub *Hyoscyamus niger* (Henbane) and *Scopola carniolica.* The galenical tincture and extract of belladonna, official in the U.S.P., are potent chiefly by virtue of their atropine content.

Chemistry. The synthetic chemist has not greatly improved upon the products of nature in this field, and although a few related derivatives have been introduced into medicine, they do not possess the wide range of therapeutic usefulness which characterizes the naturally occurring belladonna alkaloids. The natural belladonna alkaloids are organic esters formed by the combination of an aromatic acid, *tropic acid,* and complex organic bases, either *tropine* or *scopine.* The synthetic alkaloids usually contain mandelic instead of tropic acid, and a simpler organic base than tropine. The structural formulas of atropine and scopolamine and their relation to the synthetic drugs in the belladonna group appear in Table 24.

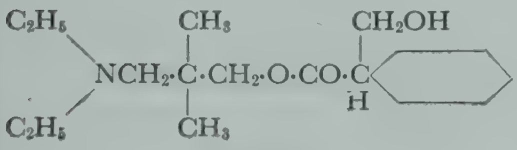
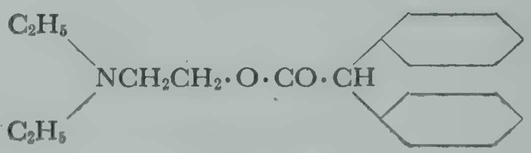
Eucatropine



Syntropan



Trasentin

Scopine differs from tropine only in having an oxygen bridge between the carbon atoms designated as 6 and 7 in the above formulas. This alteration in structure is therefore the sole chemical distinction between atropine and scopolamine. *Homatropine* is a synthetic alkaloid produced by a combination of the base tropine with a somewhat simpler organic acid than tropic acid, namely, mandelic acid. *Novatropine* is merely the methylbromide of homatropine. *Eucatropine* (euphthalmine) is another synthetic alkaloid which is a combination of mandelic acid and a piperidine base. *Syntropan* is also a synthetic drug which is an ester of tropic acid and a tertiary amino alcohol, 3 diethylamino-2, 2-dimethyl-1-propanol. *Trasentin* contains neither tropic acid nor tropine, but merely retains the ester structure and the tertiary amino base.

The chemical relationship between these various natural and synthetic drugs, and their status, occurrence and optical activity, can readily be seen by reference to Table 25.

Relation of Chemical Structure to Pharmacological Action. Numerous chemical and experimental data indicate that the basis of the selective action of atropine on autonomic structures resides not in the tropine base, which is relatively inactive, but in the tropic acid radical. The esterification of tropic acid with a tertiary amino alcohol is the essential combination. The existence of a free hydroxyl group in the acid portion of the ester is

TABLE 25

ALKALOIDS OF THE BELLADONNA GROUP AND ALLIED SYNTHETIC SUBSTANCES

ALKALOID	STATUS	OCCURRENCE	BASE	ACID	OPTICAL ACTIVITY

also important. Other aromatic acids may be substituted for tropic acid but the activity of the resulting compound is qualitatively altered. It is possible, however, to synthesize esters having parasympatholytic activity which contain neither tropic acid, scopine or tropine.

The presence of an asymmetric carbon atom in tropic acid (bold-faced C in the formula) allows for optical activity and stereoisomerism in this group of alkaloids. Scopolamine is levorotatory hyoscine and is much more active than *d*-hyoscine. Atropine is racemic, being a mixture of equal parts of the optical isomers of hyoscyamine. Inasmuch as dextrohyoscyamine has weak peripheral actions in the body, atropine owes its potency chiefly to its content of levohyoscyamine. The latter has the same central actions as atropine but is twice as powerful in its peripheral autonomic effects. The differences in behavior of atropine, dextrohyoscyamine and levohyoscyamine have been correlated with their relative rates of destruction in the body as well as with their specificity for autonomic effector organs. It is thought that levohyoscyamine exists in the younger portions of belladonna leaves and changes to racemic atropine as the plant grows older. The same change also occurs in galenical mixtures.

The close chemical relationship between atropine and cocaine deserves passing mention. *Ecgonine,* the organic base of cocaine, differs from tropine only in having a $COOCH_3$ attached at the carbon atom marked 2 in the formula for atropine. The acid portion of the cocaine ester is benzoic instead of tropic acid, and thus atropine and cocaine are tertiary amino esters of aromatic acids. Atropine, however, has only mild local anesthetic actions, and dulls rather than paralyzes sensory nerve endings. Cocaine in turn, has little or no parasympatholytic action. There are some tertiary amino esters of organic acids, however, which can act both as local anesthetics and parasympathetic depressants. The local use of belladonna in ointments, plasters and suppositories for relief of pain, though formerly rather extensive, is almost obsolete.

Mechanism of Action of the Belladonna Alkaloids. The major belladonna alkaloids, atropine and scopolamine, have two principal actions in the body. The first is on the central nervous system and the mechansim underlying these central effects is unknown. The second and more important action is on *smooth muscle* and *secretory glands* innervated by postganglionic cholinergic nerves. This latter action comprises the so-called "parasympathetic depressant" property of the belladonna drugs. All the muscarinic effects of acetylcholine and its esters can be prevented by atropine and many of the responses to cholinergic nerve stimulation can be blocked. The site of this action is directly on effector cells and not on nerve endings. The release of the chemical mediator is not prevented by atropine. Of purely academic interest is the fact that atropine under certain experimental conditions appears to exert some blocking effect on autonomic ganglia (Marazzi, 1939). This action, however, plays no part in the clinical use of the belladonna alkaloids and does not seriously challenge the previously developed concept that atropine blocks the muscarinic and not the nicotinic effects of acetylcholine. For the finer mechanism of atropine behavior, the reader is referred especially to page 340. The differences in the pharmacological properties of atropine, scopolamine and other alkaloids of this group will be mentioned as occasion arises in the following discussion.

Pharmacological Actions

Central Nervous System. Atropine produces stimulation of the medulla and higher cerebral centers. In usual clinical doses (0.5 to 1.0 mgm), this effect is manifested only by some central vagal excitation and moderate respiratory stimulation. The latter effect may be due to a direct action of atropine on the respiratory center. The rate and occasionally the depth of breathing are increased. When respiration is seriously depressed, atropine cannot be depended upon to produce excitation. Indeed, under such a circumstance, large or continued doses of atropine may cause even further depression of breathing. After doses bordering on the toxic, the central excitation produced by atropine becomes more prominent. Restlessness, irritability, disorientation, hallucinations and delirium may be evident. These effects are discussed under atropine poisoning. Ultimately, stimulation is followed by depression, and medullary paralysis is the cause of death from atropine. That all parts of the brain are not stimulated by atropine is seen in the "sedative action" exerted by belladonna alkaloids on the rigidity and tremor of parkinsonism. This action, which at present is viewed as central in origin, cannot be harmonized with an excitatory property of atropine. The drug, therefore, appears to have a primary depressant effect on certain central motor mechanisms, at least in parkinsonism. Homatropine and novatropine manifest little or no action on the central nervous system when administered in therapeutic doses.

Scopolamine, in its central actions, is usually said to contrast rather sharply with atropine. Whereas atropine first stimulates and then depresses the brain, scopolamine is a primary depressant and therapeutic doses normally cause drowsiness, fatigue and dreamless sleep. The sedative and tranquillizing effects of scopolamine have been described under preanesthetic medication. Not infrequently, however, therapeutic amounts of scopolamine produce excitement, restlessness, hallucinations and delirium. Some but certainly not all of these paradoxical reactions may be classed as idiosyncrasy or as due to the administration of scopolamine to individuals with pain. As was pointed out previously, non-analgesic sedatives given in the presence of pain are likely to cause excitement and delirium. When therapeutic doses of scopolamine are combined with morphine, as in preanesthetic medication, the pain threshold-raising property of morphine is not enhanced (Wolff and coworkers, 1940).

Scopolamine is often viewed as a respiratory depressant, but this action on the medullary respiratory center has been exaggerated. Indeed, strong evidence from clinical experiments of Waters and his associates (1938) indicates that the depression of breathing by morphine can be completely counteracted by balanced doses of scopolamine, so that otherwise poisonous amounts of morphine may be administered to man without lowering the normal respiratory exchange (page 48).

Peripheral Actions. By keeping firmly in mind the functional results of the paralysis of cholinergic nerves to smooth muscles and glands, one can accurately predict in most instances the pharmacological actions of the belladonna alkaloids. These drugs prevent the responses of smooth muscle and gland cells to cholinergic impulses. In a broad sense, the end-result often simulates overactivity of the sympatho-adrenal system—that is, it resembles the response to an injection of epinephrine. This is true because, after atropine, the normal adrenergic impulses remain dominant and unopposed.

Atropine and scopolamine differ quantitatively in their peripheral actions. Scopolamine is the stronger blocking agent for the iris, ciliary body, and certain secretory (salivary, bronchial and sweat) glands. The action of atropine is more pronounced and more prolonged than that of scopolamine on the heart, intestine and bronchiolar muscle. Atropine is more useful for its peripheral autonomic action than is scopolamine because in clinical doses it lacks a central sedative effect. Scopolamine is employed occasionally on the eye, but otherwise it is administered mainly for its central effects.

Eye. Atropine and scopolamine paralyze the sphincter muscle of the iris and the ciliary muscle of the lens to cholinergic nerve impulses and to acetylcholine. They thus cause dilatation of the pupil, *mydriasis,* and paralysis of accommodation, *cycloplegia.* The pupil is widely dilated and photophobia is present. The lens is fixed for far vision, near objects are blurred, and sometimes micropia is observed. When the drugs have exerted their full effects, the iris is no longer responsive to light and fails to react to convergence of the eyes—that is, the normal reflexes to light and accommodation are interrupted. These ocular responses are obtainable after local or systemic administration of the alkaloids. That the site of action is purely peripheral, however, is easily demonstrated by carefully applying a solution of atropine to only one-half of the cornea, whereupon dilatation of that half of the pupil alone occurs. The belladonna mydriatics differ from the sympathomimetic mydriatics (ephedrine, cocaine) in that the latter cause dilatation of the pupil without loss of accommodation. Pilocarpine and physostigmine are capable of constricting the atropinized pupil. The paralysis caused by atropine is thus not absolute. A fact of interest in comparative pharmacology is that atropine does not dilate the pupils of birds because their irides are composed of striated muscle and are paralyzed not by the belladonna alkaloids but by curare.

The intraocular pressure in normal eyes is not greatly disturbed by atropine or scopolamine. Mydriatics in general (except cocaine), however, tend to elevate this pressure especially when it is already above normal. This is true particularly of atropine due to its long duration of action. The mechanism of the rise in intraocular tension is disputed but the probable cause is the interference with the lymphatic drainage at the crucial angle of the eye due to the crowding back into this angle of the iris curtain.

Respiratory Tract. The belladonna alkaloids inhibit glandular secretions of the nose, pharynx and bronchi, and thus cause drying of the mucous membranes of the respiratory tract. This is especially prominent if there has been excessive secretion. The smooth muscles of the bronchi and bronchioles are relaxed, particularly by atropine, and this results in a slight widening of the airway and slight increase in the volume of residual air. It has been suggested that this increase in "dead space" due to bronchiolar dilatation may be the basis of the respiratory stimulation noted after atropine, but the evidence for this is not convincing. Atropine is considerably less effective than epinephrine as a bronchial antispasmodic, even when the degree of bronchoconstriction produced by faradic stimulation of the vagus nerve is used as an index of their antispasmodic potency (Figure 41).

Heart. The main effect of atropine on the heart is to alter *cardiac rate.* Atropine has a biphasic action on the heart rate. When average clinical doses are employed (0.5 to 1.0 mgm) the rate may temporarily be slowed due to a slight stimulant action of the alkaloid on the medullary vagal nuclei. This slowing is rarely marked or significant, and the change in rate is unaccompanied by changes in blood pressure, because of efficient cardiovascular compensatory mechanisms. After larger doses, usually not under 2.0 mgm in man, atropine causes an acceleration of heart rate due to the blocking of vagal effects on the S-A pacemaker. The increase in cardiac rate may be quite prominent in cases of atropine poisoning. The cardiac action of atropine is most noticeable in healthy young adults in whom the influence of the vagus on the cardiac pacemaker is at its height. At the extremes of life, in infancy and in old age, large doses of atropine may fail entirely to quicken the heart rate.

Adequate doses of atropine not only remove the heart from normal vagal control, but also prevent typical cardiac arrest from electrical stimulation of the vagus—"vagus arrest." The bradycardia or asystole produceable by injection of acetylcholine or its congeners is likewise prevented or abruptly halted by atropine. Cardiac slowing caused by other drugs, such as physostigmine, pilocarpine or muscarine, is also counteracted. Many types of *reflex* cardiac slowing mediated through the vagus nerves are prevented by adequate amounts of atropine, such as those due to inhalation of irritant vapors, to stimulation of the carotid sinus or to central stimulation of the vagal nuclei. The removal by atropine of vagal influence on the specialized tissue of the heart may also cause changes in conduction. In certain cases of partial heart block in which there is a vagal component as an etiological factor, atropine may lessen the degree of block. In some patients with complete heart block, the idioventricular rate may be accelerated by atropine. On the other hand, toxic doses of atropine may in themselves cause A-V block.

Circulation. Atropine in clinical doses counteracts completely the peripheral vasodilatation and sharp fall in blood pressure caused by acetylcholine and mecholyl. Yet when given alone, it does not have a striking or constant effect on blood vessels or blood pressure. Late in the course of atropine poisoning, the blood pressure may fall markedly, but this is due to central vasomotor depression. Toxic amounts of atropine usually, and therapeutic doses occasionally, cause an active vasodilatation of cutaneous blood vessels, especially of those in the blush area *(atropine flush).* The mechanism of this anomalous vascular response is unknown. It has been suggested that the flush is a compensatory action for the purpose of radiating heat to offset the atropine-induced rise in temperature. On the other hand, the reaction may be peripheral in origin and a direct vascular effect of the drug (Hamet, 1936). The scarlet appearance of the flushed skin, coupled with the rise in temperature which may accompany atropine intoxication, has caused the mistaken diagnosis of scarlet fever.

Although the vagal innervation of the coronary arteries is believed by some authorities to be vasoconstrictor in function, atropine is ineffective clinically in conditions of coronary vascular insufficiency and in angina pectoris. Nevertheless, atropine has been shown experimentally by competent workers to increase coronary blood flow. For example, Essex and associates (1940), employing the thermostromuhr technic in trained unanesthetized dogs, demonstrated that atropine markedly augmented coronary blood flow. An increased cardiac rate was an invariable accompaniment of the enhanced coronary blood flow, with the doses of atropine used (one to two mgm).

Gastro-intestinal Tract. The belladonna alkaloids affect both the secretory and motor activities of the gastro-intestinal tract. The *salivary secretions* are inhibited and this antisialogogic action causes the mouth to become dry, and swallowing and talking difficult. The statements that atropine lessens *gastric secretion* and lowers the acidity of the gastric juice need considerable correction. Such effects are noted only when large doses are given to experimental animals and the results cannot be interpreted to indicate that the belladonna drugs are clinically useful to diminish gastric secretion in peptic ulcer. The formation of hydrochloric acid is presumably rather under hormonal and chemical than under vagal control, and therefore one cannot expect to obtain significant changes by atropinization.

In *man,* the effect of atropine on the character of gastric secretion depends on a number of factors including the amount of drug administered, the phase of digestion and the presence or absence of disease. On the whole, the normal gastric secretion is not significantly altered by the belladonna drugs. The psychic phase of secretion, mediated by the vagus, is reduced but not abolished. The chemical phase of gastric secretion is not greatly altered by atropine. Volume may be slightly reduced, but acidity is not lowered. It is possible that the intestinal phase is somewhat inhibited, but this requires confirmation. Atropine likewise tends to diminish the continuous interdigestive secretion of the stomach. Furthermore, the duration of the effects of atropine on gastric secretion is brief when compared with that on the salivary glands.

The gastric cells responsible for the elaboration of mucin and enzymes are more directly under the influence of the vagi than are the acid-secreting cells, and full doses of atropine may decrease the concentration of these organic constituents. The secretion of an abundant gastric juice rich in both acid and proteolytic enzyme obtainable after the injection of the choline esters (mecholyl and doryl) or pilocarpine is blocked completely by atropine. Histamine-induced secretion is not impressively altered, although large doses of atropine may decrease the volume of the response. These facts offer little basis for the clinical use of the belladonna drugs in peptic ulcer or hyperchlorhydria in an attempt to reduce the volume and acidity of gastric juice.

The action of atropine on the secretion of the *intestinal glands, pancreatic juice* and *bile* is not significant and finds no therapeutic application.

The belladonna alkaloids exert definite effects on the *motility of the gastro-intestinal tract.* For an appreciation of these actions, it is necessary to recall certain facts concerning the influence of the extrinsic autonomic nerves on the movements of the enteric tract.

In general, cholinergic (parasympathetic) nerve impulses to the bowel enhance both tone and motility, but relax sphincters. The combination of these two factors favors the passage of chyme along the intestinal tract. In contrast, adrenergic (sympathetic) nerve impulses diminish the tone and motor activity of the enteric tract and contract sphincters, delaying the advance of the chyme (Table 17). Extrinsic nerve impulses alone, however, do not determine the activity of the bowel. The gastro-intestinal tract possesses a complex intrinsic neuromuscular mechanism whereby its motility is regulated, and impulses from the central nervous system serve only to allow a more delicate regulatory control. In addition, the antagonism between the two divisions of the autonomic nervous system is not as highly organized in regard to the bowel as it is, for example, in the case of the iris muscle of the eye. The depression of one system does not necessarily result in dominance of the other. This is particularly true of the sphincters of the intestine where the balanced opposition between the influences of the cholinergic and adrenergic nerves may break down entirely. It is known, for example, that stimulation either of the vagus or the splanchnic nerve to the stomach will cause increased tone when that organ is hypotonic, and decrease tone when it is hypertonic. The same principle appears true for the colon and for the sphincters of the alimentary canal. Thus epinephrine, which has little effect on the normal pyloric sphincter, enhances the tone when the sphincter is relaxed and diminishes tone when it is contracted.

The actions of autonomic drugs on gastro-intestinal motility are thus conditioned by the level of functional activity of the bowel at the time of administration of the drug. This principle holds true particularly for the belladonna alkaloids. In general, tone and peristalsis are decreased and sphincter activity is enhanced by atropine. The effects are much more prominent when spasm or hypermotility is present.

Although it is commonly stated that ordinary therapeutic doses of belladonna alkaloids have no significant influence on normal peristalsis, intubation studies combined with flouroscopy in normal human subjects indicate that clinical doses of atropine sulfate and tincture of belladonna produce definite and prolonged effects on the motor activity of the duodenum, jejunum, ileum and colon, consisting of a marked decrease in tone and in peristaltic movements, and of a less striking effect on rhythmical contractions (Elsom and Drossner, 1939). These results agree, in general, with those obtained with atropine on the human colon by Jackman and Bargen (1938).

Atropine does not significantly affect the gastric evacuation time in normal subjects. When the stomach is excessively motile and hypertonic, the alkaloid abolishes hyperactivity and restores normal peristaltic rhythm. For example, the augmentation of gastric contractions produced in man by morphine can be inhibited by atropine (Veach, 1937) (Figure 17), and the same is true for the hypermotility of the human stomach induced by injections of insulin (Quigley, 1937).

Atropine abolishes or prevents the *excess* motor activity of the gastro-intestinal tract induced by choline esters, pilocarpine, physostigmine and related parasympathomimetic drugs. For example, if an isolated strip of intestine is treated with pilocarpine to cause increased tone and spasm, the addition of atropine to the bath fluid results in immediate resumption of normal tone and peristalsis. The belladonna drugs are not effective in blocking the responses to such direct muscular stimulants as histamine and barium. Certain synthetic alkaloids appear to have more selective actions on the intestinal musculature than atropine. Although atropine blocks completely the effect of acetylcholine on the bowel, it is relatively ineffective in preventing the responses to stimulation of the vagus nerve. The physiological significance of this fact as well as a possible anatomical explanation have been discussed (page 340).

Other Smooth Muscle. On the *ureter,* the belladonna alkaloids exert an antispasmodic effect, especially noted when the ureter is in spasm. In man, atropine completely eliminates the increased ureteral tone caused by morphine (Figure 20), and the drug may also affect the normal activity of ureteral muscle. When the ureter is showing active contractions, atropine has an antispasmodic action (Figure 44).

On the *biliary ducts and gall bladder,* atropine exerts a mild antispasmodic action. This is not sufficient, however, to prevent or abolish the marked spasm and increased intrabiliary pressure induced in human beings by morphine. Both the nitrites and xanthines are more effective than atropine in this regard.

On the *uterus,* atropine has actions which are of little consequence, despite the fact that the drug is sometimes incorporated in prescriptions for dysmenorrhea. The extrinsic nerves to the uterus are relatively unimportant in the regulation of motility, and the motor response of the organ to drugs and nerve impulses differs depending on manifold factors, particularly the species involved, the presence of pregnancy and its stage. For these reasons, no didactic statement regarding the influence of atropine can be given, although in general it tends to be mildly antispasmodic.

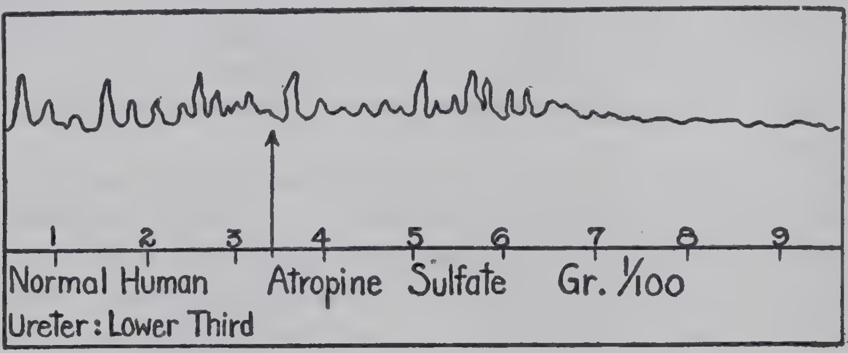

Figure 44. *The effect of atropine sulfate on the normal human ureter.*

Kymographic tracings obtained by means of ureteral catheter and water tambour; time in minutes. Note that within three minutes after the subcutaneous administration of 0.6 mgm of atropine sulfate the amplitude of contractions and ureteral tone are depressed. (After Ockerblad, Carlson and Simon, 1935. Courtesy of the *Journal of Urology.*)

On the *urinary bladder,* atropine exerts a depressant effect on the detrusor muscle, especially in conditions of hypertonus. This is the basis for its use in enuresis.

Sweat Glands. Atropine is a potent inhibitor of the sweat glands despite the vasodilatation it may cause in certain cutaneous areas. Sweating is suppressed and the skin becomes hot and dry. The prevention of insensible perspiration may be sufficient to elevate the body temperature, although hyperthermia is not prominent unless toxic amounts of belladonna have been taken. The anhidrotic action of atropine remained a pharmacological anomaly for many years due to the fact that sweat glands lacked parasympathetic innervation. The stimulation of sweating by pilocarpine likewise remained unexplained. With the demonstration that the nerves to sweat glands are cholinergic in function, the response of these structures to parasympathomimetic agents at once became clear.

Body Temperature. The increase in body temperature following the administration of belladonna alkaloids is significant only when large doses are given. Hyperthermia from moderate doses, nevertheless, may occur in children and infants and the term "atropine fever" has arisen to describe this phenomenon (White, 1929). Suppression of sweating is the main factor in the production of fever, although restlessness produced by toxic doses may contribute. It has also been suggested that atropine may cause fever by a central effect on temperature regulation. In atropine poisoning in infants, the temperature may reach the alarming height of 109 F. Animals which do not sweat, such as the dog, show no fever after atropine.

Local Analgesic Effects. The local anesthetic action of atropine has been mentioned under the discussion of the chemistry of the drug. The use of belladonna alkaloids for their anodyne property is practically obsolete.

Miscellaneous Actions. In man, atropine in ordinary doses does not significantly alter the *basal metabolic rate* or respiratory quotient. Edsall and Means (1914), however, noted in a study of two patients that atropine in doses of 1.2 mgm caused a definite rise in metabolism, a marked fall in alveolar carbon dioxide and a rise in alveolar ventilation. Despite the many contradictory experimental reports on the effect of atropine on carbohydrate metabolism, the level of *blood sugar* is not altered by clinical doses. Belladonna drugs do not affect the *secretion of milk*. Stockman (1927), however, has reported that atropine decreases the yield of milk when given to women post partum in doses of 0.6 mgm twice daily. This observation requires confirmation. *Lacrimation* is depressed due to inhibition of the tear glands, but this action of atropine is not as prominent as on the salivary glands. *Leukocytosis* may occur from atropine medication in children. *Voluntary muscles* of mammals are not directly affected by belladonna.

Tolerance. Tolerance to the belladonna drugs occurs in man to a limited extent. This is noticed particularly in patients with parkinsonism who eventually receive daily doses of atropine or scopolamine which, if given to the uninitiated, would result in poisoning. *Habituation* and *addiction* do not occur, although vomiting, malaise, perspiration and salivation have been recorded in patients with Parkinson's disease upon sudden withdrawal of the large doses required for therapeutic benefit.

Some species of animals, especially rodents and marsupials, are tolerant to large doses of belladonna alkaloids. Rabbits, for example, thrive on a diet containing belladonna leaves and do not manifest toxic effects. It appears that the serum and liver of tolerant animals possess the ability rapidly to destroy these alkaloids.

Absorption, Fate and Excretion. The belladonna alkaloids are absorbed rapidly from the gastro-intestinal tract. They also enter the circulation when applied locally to the mucosal surfaces of the body. Absorption occurs from the eye, and to some extent from the intact skin. Mydriasis and partial paralysis of accommodation lasting several days have occurred from the use of belladonna plasters. Atropine disappears rapidly from the blood and is distributed throughout the entire body. In the tissues, especially in the liver, the alkaloid is destroyed in large measure by hydrolysis of the ester to tropine and tropic acid. The remainder, amounting in man to about one-third the ingested dose, is excreted mainly within 14 hours by the kidneys. Traces are found in other secretions including the milk. Atropine readily crosses the placental barrier and enters the fetal circulation. The appearance of the alkaloids of belladonna in the urine allows for their recognition by a rapid and sensitive presumptive test. A single drop of urine placed in a cat's eye will dilate the pupil if atropine (0.0003 mgm) or scopolamine (0.00002 mgm) is present.

Poisoning by Belladonna Alkaloids. Atropine and scopolamine are the most important drugs of the belladonna group from the standpoint of poisoning. Intoxication frequently occurs in the clinical use of these agents. Children are especially susceptible and many cases of poisoning have resulted from the conjunctival instillation of these alkaloids, because absorption occurs from the nasal mucosa after the drug has entered the nasolacrimal duct or from the intestinal tract if it is swallowed. Serious poisoning has occurred from the erroneous substitution of scopolamine or atropine for the weaker homatropine. If the patient who is using belladonna in ascending doses for spastic states of the bowel is not warned concerning early signs of intoxication, unpleasant consequences may follow. The atropine in medicines given for enuresis in children has caused poisoning. Finally, berries or seeds containing belladonna alkaloids are occasionally ingested by children in toxic amounts, or a brew made from the seeds of Jimson weed may cause poisoning.

Hughes and Clark (1939), in an article reporting two instances of stramonium poisoning from the drinking of tea made from Jimson weed seeds, cite the following cases which occurred in 1676 and are probably the first to have been reported in the United States: "This being an early Plant, was gather'd very young for a boil'd salad, by some of the Soldiers sent thither, to pacifie the troubles of Bacon; and some of them ate plentifully of it, the effect of which was a very pleasant Comedy; for they turned natural Fools upon it for several Days. One would blow a Feather in the Air; another would dart straws at it with much Fury; and another stark naked was sitting up in a Corner, like a Monkey grinning and making Mows at them; a Fourth would fondly kiss and paw his Companions, and snear in their Faces, with a Countenance more antik than any in a Dutch Droll. In this frantik Condition they were confined, lest they in their Folly should destroy themselves; though it was observed that all their Actions were full of Innocence and Good Nature. Indeed, they were not very cleanly; for they would have wallow'd in their own Excrements, if they had not been prevented. A Thousand such simple Tricks they play'd and after Eleven Days, return'd themselves again, not remembering anything that had pass'd."

Fatalities from atropine and scopolamine are rare despite the therapeutic potency of low doses of these drugs, although Morton (1939) records two fatalities among eight cases of atropine poisoning in children. Of all the potent alkaloids, atropine has one of the widest margins of safety. Scopolamine is usually stated to be more toxic than atropine, although the evidence for this belief requires reexamination. Idiosyncrasy, nevertheless, is more commonly manifested toward scopolamine than atropine, and ordinary therapeutic doses may sometimes cause alarming intoxication. Mild toxic effects not infrequently noted after scopolamine have been attributed to chemical decomposition, but it appears that even the purest samples of the drug may show some variations in clinical action and toxicity.

The amounts of atropine required to cause definite symptoms of overdosage can be seen from the following table:

0.5 mgm	Slight cardiac slowing; some dryness of mouth.
1.0 mgm	Definite dryness of mouth and thirst; slowing of heart rate followed by some acceleration; mild dilatation of pupil.
2.0 mgm	Rapid heart rate; palpitation; xerostomia; inhibition of sweating; pupils dilated; some blurring of near vision.
5.0 mgm	All of above symptoms marked; speech disturbed; difficulty in swallowing; restlessness combined with fatigue; headache; dry and hot skin.
10.0 mgm and above	Above symptoms more marked; pulse rapid and weak; iris practically obliterated; vision very blurred; skin flushed, hot, dry, and scarlet hue; ataxia; excitement; restlessness; hallucinations, delirium and coma.

The *fatal dose* of atropine is not known but it is probably in the neighborhood of 100 mgm for adults and 10 mgm for young children. Survival has been reported after much larger doses and a case of recovery is on record after 500 mgm of scopolamine.

Symptoms. These develop promptly after ingestion of the drug. The mouth becomes dry and burns, and swallowing and talking are difficult or impossible. Marked thirst is present. The vision is blurred and photophobia is prominent. The skin is hot, dry and flushed. A rash may appear especially over the face, neck and upper part of the trunk, and desquamation may follow. The atropine rash is more likely to occur in children. The body temperature rises and in infants may reach the alarming height of 107 F or more. The pulse is weak and the cardiac rate is very rapid, although in infants and old people this acceleration may not be prominent. Palpitation is experienced and the blood pressure is elevated. Urinary urgency and difficulty in micturition are sometimes noted.

The patient is restless, excited and confused and exhibits weakness, giddiness and muscular incoordination. Gait and speech are disturbed. Nausea and vomiting are sometimes noted. The behavior and mental symptoms may suggest an acute psychosis. Memory is disturbed, orientation faulty, hallucinations (especially visual) common, sensorium clouded, and mania or delirium not infrequent. The diagnosis of acute schizophrenic episodes or alcoholic delirium has been mistakenly made, and some patients have been committed to psychopathic institutions. Atropine and scopolamine do not differ in these respects although depression follows the excitement and psychotic phenomena somewhat more readily after scopolamine.

The syndrome described persists for many hours and may completely disappear only after several days have passed. Depression and circulatory collapse result only in cases of severe intoxication. The blood pressure declines, respirations become inadequate and death due to respiratory failure occurs after a period of paralysis and coma.

Diagnosis. Careful analysis of the symptoms readily demonstrates that widespread paralysis of those structures innervated by postganglionic cholinergic nerves has occurred and this should immediately arouse the suspicion of belladonna poisoning. Particularly significant are the dry mucous membranes, widely dilated unresponsive pupils, tachycardia, cutaneous flush and fever. The last two features are prominent in children and should not be mistaken for an acute exanthematous illness such as scarlet fever. Atropine-induced leukocytosis may contribute to the possibility of such an error. The mental symptoms, however, may distract the physician's attention from the obvious peripheral autonomic signs. Any patient with an acute onset of bizarre mental and neurological symptoms should be suspected of drug poisoning, especially by atropine. History of belladonna medication is helpful in corroborating the diagnosis. If one is still in doubt, the hypodermic injection of 10 to 30 mgm of mecholyl (Dameshek and Feinsilver, 1937) may prove whether poisoning by atropine or scopolamine exists. If the flushing, salivation, sweating, lacrimation, intestinal hyperactivity, etc., characteristically seen after mecholyl do not occur, belladonna intoxication almost certainly is present, because atropine antagonizes all muscarinic effects of mecholyl.

Treatment. When the poison has been taken orally, gastric lavage with solutions containing alkaloidal antidotes may be undertaken. Potassium permanganate is ineffective in destroying atropine. Pilocarpine may be given in doses of five mgm and repeated at intervals until the mouth is moist. This adds to the patient's comfort and relieves the visual symptoms to some extent. Central effects of the poison, however, are not influenced by pilocarpine and represent the source of danger. If marked excitement is present, the short-acting barbiturates, chloral hydrate or paraldehyde may be used for their sedative action. Large doses should not be employed, unless essential, because of the danger that their central depressant action may coincide with the depression occurring in the late stage of belladonna poisoning. Central nervous system stimulants may be tried if the patient is observed after depression has developed. Artificial respiration or inhalation of carbon dioxide and oxygen may be necessary if respiratory depression is severe. Remaining therapy is purely symptomatic. Ice bags and alcohol sponges aid in reducing the fever in children. Careful nursing is essential.

Preparations, Doses and Routes of Administration. *Tincture of Belladonna,* U.S.P., B.P., is a widely employed preparation obtained from belladonna leaves. Its average dose is 0.6 cc which is the equivalent of approximately 0.2 mgm of atropine. *The Extract of Belladonna,* U.S.P., B.P., may be obtained in *pill* form or as a *powder* for capsules. Its dose is 0.015 gram.

Belladonna Leaf (Deadly Nightshade Leaf), *Belladonna Root* (Deadly Nightshade Root) and *Fluidextract of Belladonna Root* are also official in the U.S.P. and B.P. The average oral doses for adults of these three drugs are as follows: *Belladonna Leaf,* 0.06 gram; *Belladonna Root,* 0.045 gram; *Fluidextract of Belladonna Root,* 0.05 cc. These preparations, however, are little used, and preference is given to the tincture or extract of belladonna leaves and to the pure alkaloids. The U.S.P. and B.P. also contain a *plaster* and *ointment* form of belladonna, but these have few if any valid uses.

Atropine, U.S.P., B.P., the main alkaloid of belladonna, is available as such or as the readily soluble salt, *Atropine Sulfate,* U.S.P., B.P., in tablet or powder form. The usual adult dose is 0.3 to 1.0 mgm. The usual route of administration is oral, but solutions of atropine sulfate may be injected subcutaneously or intravenously. *Scopolamine* (hyoscine) is marketed as the readily soluble salt, *Scopolamine Hydrobromide* (Hyoscine Hydrobromide), U.S.P., B.P. The adult dose is 0.5 mgm. Scopolamine may be given orally or parenterally by injection.

The official stramonium preparations and their doses are as follows: *Stramonium* (U.S.P., B.P.), 0.075 gram; *Extract of Stramonium* (U.S.P.), 0.02 gram, available in pill and powder form; *Tincture of Stramonium* (U.S.P., B.P.), 0.75 cc.

The official preparations and doses of hyoscyamus (from *Hyoscyamus niger*) are as follows: *Hyoscyamus* (Henbane), U.S.P., B.P., 0.2 gram; *Extract of Hyoscyamus* (Extract of Henbane), U.S.P., B.P., 0.02 gram, available in pill and powder form; *Fluidextract of Hyoscyamus* (Fluidextract of Henbane), N.F., B.P., 0.2 cc; *Tincture of Hyoscyamus* (Tincture of Henbane), U.S.P., B.P., 2.0 cc. These drugs are rarely employed in modern therapeutics and are not recommended because of their uncertain actions.

The synthetic alkaloids related to the belladonna group are discussed at the end of this chapter. These drugs include *homatropine, eucatropine, eumydrine, novatropine, syntropan* and *trasentin.*

Therapeutic Uses

The belladonna alkaloids enjoy a broad range of therapeutic use in medicine and surgery. The clinical applications of these drugs are a direct outgrowth of the various pharmacological actions outlined in the preceding paragraphs, and may be discussed in parallel order. The ubiquitousness of the effects of belladonna, however, is also its major drawback because it is often impossible to confine the action of the drug to those structures at which therapy is directed. Thus, side-actions must be tolerated during belladonna medication in order to secure certain desired responses. For example, when the abolition of intestinal spasm is sought, coincident dry mouth and suppression of sweating must be viewed as entirely unrelated but unavoidable phenomena.

Clinical Uses of the Central Actions. Scopolamine is more widely employed than atropine for its central effects. Nevertheless atropine is occasionally injected as a *respiratory stimulant.* For this purpose, atropine sulfate may be given subcutaneously in a dose of 0.5 to 1.5 mgm, but should not be repeated. In cases of severe central depression, other drugs than atropine are to be preferred. Therapeutic doses of scopolamine do not influence respiration.

The *sedative* and *tranquillizing* properties of scopolamine are useful especially in patients who are restless and agitated, as in *delirium tremens, maniacal states, cardiac and hyperthyroid psychoses,* etc. Scopolamine has also been employed to obtain criminal confessions. The value of scopolamine combined with morphine for preanesthetic medication has been discussed elsewhere. The depression caused by this combination of drugs is known as "twilight sleep," formerly widely used in *obstetrical anesthesia.* Its dangers far outweigh its advantages. The administration of scopolamine in conjunction with barbiturates in obstetrics has received considerable attention. Only persons specially trained in obstetrical anesthesia should routinely employ these potent drug combinations. Scopolamine is also of value in the *withdrawal treatment* of narcotic or alcoholic addicts (page 216). The usual sedative dose of scopolamine is 0.5 mgm of the hydrobromide salt, given orally or subcutaneously. Mild paradoxical responses or idiosyncrasy are not infrequent. If pain is present, scopolamine hypnosis may cause delirium unless analgesics are concomitantly prescribed.

In *paralysis agitans and postencephalitic parkinsonism,* therapy with belladonna alkaloids is one of the few measures that offers some measure of symptomatic relief. Atropine was apparently first recommended by Charcot, and scopolamine was introduced for the same purpose by Erb in 1901. A majority of patients experience improvement after these drugs are given. Tremor, muscular rigidity, abnormal gait, speech and posture, oculogyric crises, dysphagia, hyperhidrosis and sialorrhea respond favorably, and consequently the mental outlook often improves. Treatment is purely palliative and the course of the disease is not altered. The preparations usually employed are atropine, scopolamine, and tincture or extract of stramonium. No fixed dosage can be recommended but the important point is that the amount used varies with each patient and must be sufficient to afford optimal benefit. Ordinarily, very large doses are required and are reached by starting with small amounts which are then gradually increased. One may have to approach the limit of tolerance before real relief appears and mild toxic symptoms of annoying dry mouth and slightly impaired vision may be experienced. The local application of eserine may be necessary to overcome the mydriasis. Ultimate doses as high as five mgm or more of scopolamine or atropine, and five cc of tincture of stramonium, three times daily, are not unusual. The highest recorded daily dose of atropine is 54 mgm; of scopolamine, 195 mgm (!) (Hall, 1937; Cohen and Craw, 1937). Considerable tolerance obviously develops because such large amounts would be highly toxic to the uninitiated. Patients on high doses may be very sensitive to hot weather. Glaucoma is a definite contraindication to the employment of these alkaloids. The combined use of benzedrine and atropine may give more relief than atropine alone, especially in regard to oculogyric crises (page 446).

"Bulgarian Treatment" of Parkinson's Disease. This treatment consists in the use of an extract of belladonna root rather than of the pure alkaloids or galenical preparations of the leaf. It is claimed that better results are obtained and that unpleasant side-actions are fewer. There is no good evidence that Bulgarian belladonna root is more satisfactory than roots grown elsewhere. While it is possible that the particular combination of alkaloids of belladonna found in the root of the plant may be more beneficial to some patients than the use of other preparations, considerably more evidence is necessary to establish this point.

Belladonna alkaloids, particularly scopolamine, have been tried in other spastic and rigid states (*progressive spastic paralysis, spastic paraplegias due to birth injuries,* etc.) and variable degrees of symptomatic relief may sometimes be obtained.

Clinical Uses of the Peripheral Actions. *Ophthalmological Applications.* When the effects of belladonna alkaloids on the eye are desired, local rather than systemic administration is selected. Mydriasis is often necessary for proper examination of the retina and optic disc, and is valuable in the therapy of acute iritis, iridocyclitis, and keratitis of both the ulcerative and interstitial type.

Alternated with miotics, the belladonna mydriatics are employed for breaking up or preventing adhesions between the lens and the iris. Complete cycloplegia may be necessary in iridocyclitis, choroiditis and for accurate measurement of refractive errors. The usual preparation of *atropine* employed in ophthalmological work is a one per cent aqueous solution of the sulfate salt, although the alkaloid may be used as the free base in a one per cent solution in oil, or as a one per cent ointment. One or two minims of the aqueous or oily solution are instilled in the conjunctival sac, and pressure exerted in the region of the inner canthus will prevent the drug from reaching the nasal mucosa, where it may be absorbed in amounts sufficient to cause untoward systemic effects. This maneuver is particularly advisable in children. Gelatin discs containing atropine are sometimes employed instead of the solution and are inserted in the conjunctival space.

Atropine is repeated at intervals of several hours depending upon the degree of paralysis desired. Mydriasis without paralysis of accommodation is obtainable with a smaller amount of the drug than that necessary for cycloplegia. The pupillary dilatation produced by a full single instillation of atropine in healthy eyes persists for days, often ten or more; the cycloplegia, for four or five days. During acute inflammation, however, medication may have to be repeated two or three times a day. If satisfactory results are not obtained with a one per cent solution, the strength may be raised cautiously to two per cent, or the atropine may be combined with cocaine, benzedrine or paredrine. Atropine occasionally may cause local irritation of the eyes and in susceptible persons it may produce swelling of the eyelids and conjunctivitis. Upon continued atropine medication, conjunctivitis may become chronic and resemble trachoma.

Scopolamine hydrobromide may be substituted for atropine, particularly if the latter causes local irritation. A 0.1 to 0.5 per cent solution is used, and systemic absorption should be prevented by pressure over the lacrimal sac for five minutes after each instillation. Mydriasis is somewhat shorter in duration and intraocular pressure is affected less markedly than is the case after atropine.

When mydriatics are prescribed, dark glasses should be worn by the patient to lessen photophobia. Physostigmine is often helpful in overcoming belladonna mydriasis and one minim of a 0.2 per cent solution is applied several times daily until the pupil has returned to normal. A one per cent solution of pilocarpine nitrate may be employed similarly.

The main danger in the ophthalmological use of the belladonna drugs is that of increased intraocular pressure. An attack of glaucoma may be precipitated by the improper selection of a mydriatic agent, and blindness may ensue. Great care must therefore be exercised in instilling atropine in the eyes when there is a suggestion of increased intraocular tension. The pressure should be tested beforehand. Atropine should not be given to patients over 40 years of age, as a general rule, unless this drug is specifically indicated. A summary of the uses and dangers of mydriatic and miotic alkaloids in ophthalmology has been given by Gifford (1939).

The temporal characteristics of the mydriatic effects of atropine and scopolamine in comparison with homatropine, eumydrine and euphthalmine are presented in Table 26.

Respiratory Tract Disorders. Bronchial Asthma. Theoretically, atropine should be very effective in this syndrome because it dilates and dries the bronchial tree, and should thus counteract the bronchial spasm and excess glandular secretion. The results of atropine medication in acute attacks, however, are far from brilliant. Although an occasional patient responds satisfactorily to large doses, the drug cannot be relied upon to give relief in severe cases. Rather one uses epi-

Table 26

MYDRIATICS OF THE BELLADONNA GROUP

Drug	Strength of Solution %	Mydriasis		Paralysis of Accommodation	
		Maximal (hours)	Recovery (days)	Maximal (hours)	Recovery (days)
Atropine Sulfate	0.5–1.0	½	5 to 12	2 to 4	4 to 5
Scopolamine Hydrobromide	0.1–0.2	½	3 to 5	1 to 3	2 to 4
Homatropine Hydrobromide	2.0	½	½ to 1½	1 to 2	1
Eumydrine	0.5	½	½ to 1	1	1 to 3
Euphthalmine	5 to 10	½	½	......	......

nephrine and other measures. The belladonna alkaloids are time-honored remedies in asthma, nevertheless, and are often incorporated in various mixtures given for chronic asthma, or during the free period between acute episodes to diminish the frequency or severity of attacks.

The burning of *stramonium leaves* for the relief of asthma was introduced from India in 1802 by General Gent. This old remedy is occasionally employed today and may be helpful to some patients when used early or in mild attacks. Stramonium (2 parts), potassium nitrate (1 part), and powdered anise (1 part) are mixed together and one teaspoonful ignited, the smoke being inhaled. Some of the alkaloids of the burning leaf as well as some nitrite are contained in the smoke, and these agents tend to relieve bronchiolar spasm. The smoke, however, is irritating to certain individuals and may occasionally increase susceptibility to asthmatic attacks. The odor is rather unpleasant and clings about the room for some time. Proprietary asthma powders and cigarettes usually contain stramonium.

Coryza and Hay Fever. In acute rhinitis, coryza and hay fever, atropine may be helpful through inhibiting the nasal and lacrimal glands and thus giving symptomatic relief from distressing excessive secretions. Proprietary "cold" tablets often contain atropine for this purpose. The course of the illness is not altered by the drug.

Miscellaneous Respiratory Uses. The *preanesthetic employment* of atropine or scopolamine to prevent excessive secretions of the respiratory tract during inhalation anesthesia has been mentioned. *Bronchorrhea* from other causes may yield symptomatically to these alkaloids. In patients too feeble or exhausted to raise obstructing mucus from the trachea or bronchi, atropine may have to be employed if suction is not feasible. *Cardiac asthma* does not respond to atropine because the pulmonary edema which characterizes this syndrome is not the result of glandular secretion but is due to vascular stasis secondary to left ventricular failure.

Cardiovascular Uses. Atropine is occasionally of some value in the treatment of *premature systoles.* The alkaloid is also serviceable in patients experiencing *bradycardia* or complete systolic arrest with *syncope* as a result of abnormally active *carotid sinus reflexes.* Weiss and associates (1936) have shown that therapeutic doses of atropine abolish the vagal type of syncope in patients with hyperactive carotid sinus mechanisms, but have no effect either upon the depressor or cerebral forms of attacks. *Abnormal slowing* of the heart due to such poisons as pilocarpine, physostigmine, choline esters and certain species of mushrooms can be counteracted by atropine in full doses (2.0 mgm).

In *complete heart block* with syncopal attacks (Stokes-Adams disease), atropine may sometimes give relief, but more often the drug fails to affect the idioventricular rhythm. This is probably due to the fact that the vagus nerves do not innervate the human ventricle and also have little or nothing to do with the etiology of the arrhythmia in the vast majority of cases. Some acceleration of the ventricular rate may be regularly demonstrated in patients with complete heart block if atropine is given intravenously in doses of two mgm (Gilchrist, 1933). The drug, however, is least helpful when it is most needed, because at low initial ventricular rates the response to atropine is not significant. There is a rare type of auriculoventricular dissociation, however, probably of reflex origin, in which relatively small doses of atropine (0.5 to 1.0 mgm) given two or three times daily may abolish the block.

The higher the initial resting rate, the greater is the ventricular acceleration obtained. It has been suggested that the inherent rhythmicity of the specialized tissue at the center of idioventricular impulse formation determines the degree of acceleration from atropine in complete heart block. When the lesion producing the arrhythmia is high in the conduction system, a greater response will occur after atropine than when the new center of impulse formation is at a lower level. Epinephrine, in contrast to atropine, has a much greater accelerating effect in complete heart block when the initial ventricular rate is slow. The change in *auricular rate* after atropine in complete heart block is variable. Acceleration usually occurs but is unrelated to initial rate or ventricular response.

Atropine is sometimes useful for the prevention of *nitritoid crises* occurring in the course of arsphenamine therapy for syphilis. A subcutaneous injection of one or two mgm of the alkaloid is given 20 minutes before the arsenical. Epinephrine, however, is more effective and less unpleasant for this purpose.

Gastro-intestinal Disorders. In the therapy of *peptic ulcer,* no decrease in acidity or volume of gastric juice can reasonably be expected from belladonna alkaloids. On the other hand, tincture or extract of belladonna and atropine sulfate are serviceable in this disorder to control excess motor activity such as hyperperistalsis, pylorospasm and reflex spasticity of the colon. The drugs, however, are merely adjuvants to the more important dietary and medical management of peptic ulcer. Belladonna is also helpful in treating spastic constipation arising from various causes. In *mucous colitis, dysenteries, nonspecific chronic ulcerative colitis,* etc., these alkaloids are useful to control spasm, reduce hyperirritability, relieve pain and decrease the frequency of bowel movements. In *biliary colic,* atropine may be employed but satisfactory relief of symptoms is not the rule. Intravenously injected atropine (one to three mgm), given once or twice daily for several days, has been reported to give relief in the *gastric crises* of tabes dorsalis (Alajouanine and Harowitz, 1932). This observation requires confirmation.

Pylorospasm and *cardiospasm* may also be lessened or abolished by atropine. The roentgenologist sometimes finds this alkaloid of service in gastro-intestinal *x-ray studies* when there is difficulty in distinguishing between functional spasm and defects due to organic disease. Atropine administration has been recommended as a differential *diagnostic test* in questionable cases of *appendicitis.* If pain and tenderness persist after a hypodermic injection of 0.6 mgm of atropine, the likelihood of appendicitis is increased. Miscellaneous syndromes in which belladonna is used include *lead colic, morphine-induced obstipation* and *functional constipation* resulting from long train or auto trips.

Certain features of belladonna medication for disorders of the gastro-intestinal tract deserve special mention. Full dosage and long-continued administration are usually necessary in chronic cases. The optimal amount must be found for each patient, and varies greatly in different individuals. Some persons obtain benefit only when the dose used is just short of that which causes toxic symptoms. The tincture of belladonna is a convenient preparation because its dose can readily be adjusted. The usual practice is to start with small quantities, about 0.3 to 0.6 cc (five to 10 minims) three times daily, one-half hour before meals. The amount is then elevated at the rate of 0.06 cc (one minim) per dose per day until optimal relief is afforded. This may necessitate from two to three cc (30 to

45 minims) two or three times daily. Dry mouth may appear before satisfactory effects on the bowel are obtained, but this does not constitute a reason for decreasing the dose. Medication may have to be continued until evidence of intoxication is manifest, especially early difficulty in vision, dizziness, palpitation and nausea. The dose is then lowered to a level just below that which causes these symptoms. Failure to prescribe amounts of belladonna sufficient to act satisfactorily on the bowel has caused much unnecessary disappointment in the use of this valuable drug. The patient must be forewarned concerning the symptoms produced by belladonna and when to stop his medication. Otherwise serious poisoning may develop.

Urinary Tract Disorders. The antispasmodic action of atropine on the ureter may occasionally be employed to give relief from *ureteral colic.* The alkaloid is particularly indicated if morphine is employed because it will counteract the additional spasm of the ureter caused by morphine. In disturbances of the urinary bladder, especially in *enuresis* in children, atropine may give symptomatic relief by inhibiting excess detrusor tone. The pressure in the bladder of the child is lowered and the frequency of contractions decreased. Belladonna has been employed in other disorders of vesical function but the results are not brilliant. Langworthy (1936) found it of value in relieving the *urgency and frequency* of urination in patients with spastic paraplegia. The mechanism of action of atropine on the urinary bladder and sphincters is not always clear, probably due to the complex neurogenic control of the voluntary and autonomic components of these structures.

Miscellaneous Uses of Atropine. Atropine is employed more or less empirically in *dysmenorrhea* due to uterine spasm, and in certain cases it may afford relief. For this purpose the drug is given orally in 0.5 mgm amounts three times daily for two days preceding the expected onset of menstrual flow, and is continued for two days after menstruation has started. The alkaloid is useful for suppression of *excessive salivation,* such as may occur in heavy metal poisoning. Although atropine is an effective *anhidrotic,* the suppression of sweating is rarely employed in modern therapeutics. The belladonna drugs are helpful within limits in overcoming some of the symptoms of *poisoning* by pilocarpine, eserine, choline esters, and certain species of *Amanita.* Atropine has been employed prior to *encephalography* in doses of 1.3 mgm to lessen the symptoms which follow the injection of air into the subarachnoid space, such as nausea, vomiting, headache and excessive sweating. Good results have been reported by Scott (1939) in over 100 cases.

SYNTHETIC SUBSTITUTES FOR BELLADONNA ALKALOIDS

Novatropine

This drug is homatropine methyl bromide, and represents the mandelic acid ester of tropine methyl bromide. It differs from homatropine only by having a CH_3 and a Br radical attached to the N of tropine (Table 24). Novatropine is said to be less active than atropine on the central nervous system. Like homatropine, it is a weaker and less toxic autonomic blocking agent than atropine. The drug is used mainly for gastro-intestinal disorders for which it can be employed in the same manner as atropine.

Novatropine, N.N.R., is a white, bitter, water-soluble powder and is marketed for oral use in tablets containing 2.5 mgm.

Syntropan

This synthetic alkaloid is the phosphate salt of the tropic acid ester of a tertiary amino alcohol (Table 24). Its close resemblance to the local anesthetics in chemical structure is obvious, and the amino-containing base is the same as that used in the local anesthetic, *larocaine*. Syntropan is practically devoid of mydriatic action, being only $1/1000$ as effective as atropine and shorter in duration of action. Inhibition of pilocarpine-induced salivation in rabbits is manifested by syntropan to only $1/100$ the extent of atropine. The blocking of vasodepressor effects in cats is only $1/500$ as prominent with syntropan as with atropine. In sharp contrast, the spasmolytic action of the drug on isolated rabbit intestine is about $1/100$ to $1/20$ that of atropine (*see* Fromherz, 1937; Clark and coworkers, 1939).

The main action of syntropan is an antispasmodic one on smooth muscle, especially of the gastro-intestinal tract. The drug has been used to relieve gastro-intestinal spasm, vesical and urethral spasm and dysmenorrhea. The relaxation of smooth muscle is perhaps accomplished rather by a direct effect on muscle, in a manner similar to that of papaverine and nitrites, than by a specific parasympatholytic property, as is the case with atropine. The use of syntropan allows more discrete therapeutic results and one can obtain relief of spasm without accompanying mydriasis, dry mouth, and changes in cardiac rate.

Syntropan, N.N.R., a white, crystalline, water-soluble powder, is marketed for oral administration in tablets containing 50 mgm, and for hypodermic injection in ampules containing 10 mgm of drug in one cc of solution. The single dose may be repeated three or four times daily.

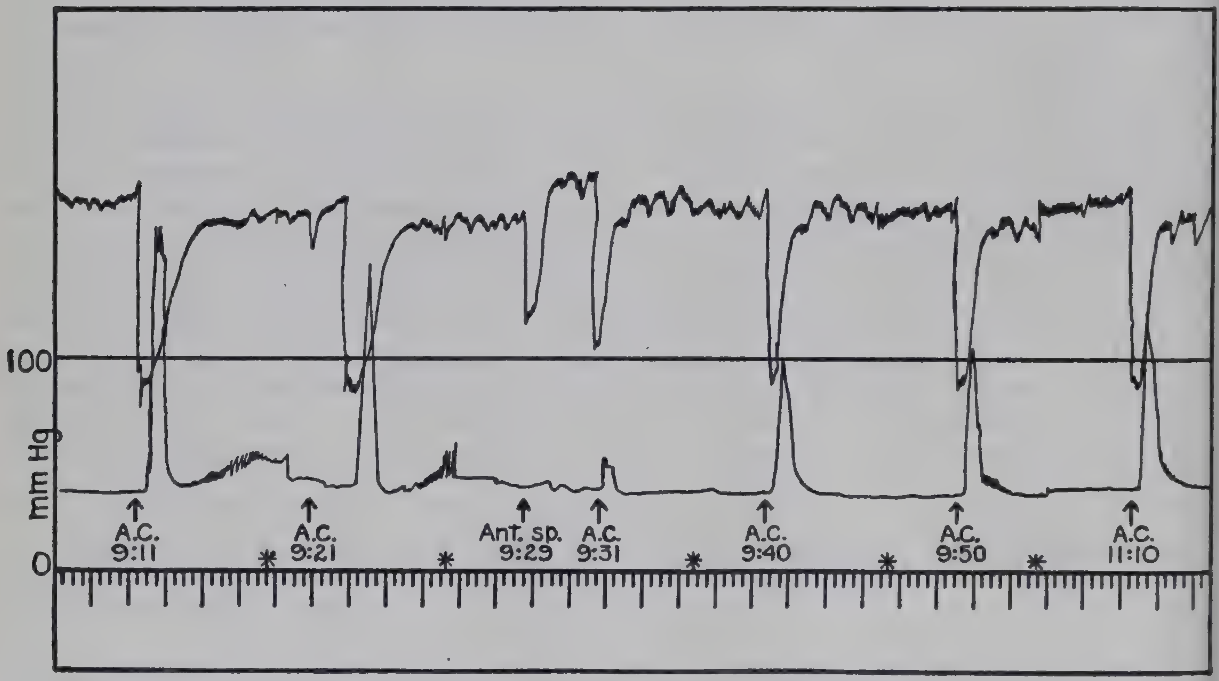

FIGURE 45. *The selective antispasmodic action of synthetic atropine substitutes.*

Anesthetized cat prepared for recording of carotid blood pressure and intestinal tone. Water manometer attached to balloon in jejunum under pressure of seven centimeters of water. Time in minutes. Control intravenous injection of acetylcholine (0.01 mgm/kg) causes a transitory increase in intestinal tone and fall in blood pressure. Two minutes after the intravenous injection of the antispasmodic (trasentin, 2.0 mgm/kg), the administration of acetylcholine is without effect on the bowel but still lowers the blood pressure almost as much as previously. Note how rapidly the antispasmodic action is lost when the drug is administered by vein. Observe that the rapid intravenous injection of the antispasmodic is accompanied by a transitory fall in blood pressure.

Synthetic atropine substitutes (see text) may be of value for their antispasmodic action when it is desired to avoid the cardiovascular, glandular and pupillary actions of the belladonna alkaloids. (Mountain, 1937.)

Trasentin

This synthetic alkaloid is another antispasmodic drug which has been recommended as a substitute for belladonna. Chemically, trasentin is the hydrochloride of the diethylamino ethyl ester of diphenylacetic acid. It thus contains neither the tropic acid nor tropine base of atropine, and has the type-structure of the local anesthetics (Table 24). Indeed, it has local anesthetic properties. One may wonder whether the anodyne action which is reported to occur from the use of trasentin in patients with peptic ulcer may not, in some measure, be due to a local anesthetic action of the drug. Trasentin accomplishes its antispasmodic effect on smooth muscle by a direct action in a manner similar to that of syntropan rather than through a highly selective parasympatholytic property, as is the case with atropine. Thus trasentin can counteract direct muscular stimulants like barium and pituitrin more effectively than does atropine, but it is much less potent against parasympathomimetic drugs such as the choline esters (*see* Johnson and Reynolds, 1937; Mountain, 1937; Necheles and coworkers, 1939). It lacks the mydriatic, cardiac and glandular effects of the belladonna alkaloids and thus, like syntropan, is more selective in its therapeutic action on smooth muscle (Figure 45). Trasentin apparently disappears rapidly from the body and has no cumulative action (Samaan and Saad, 1938).

Trasentin has been used especially for the same gastro-intestinal disorders in which atropine is indicated (Einhorn, 1938; Spier and associates, 1939). It has also been employed in spastic dysmenorrhea (Kurzrok and coworkers, 1940), and in spastic conditions of the gall bladder and biliary ducts, ureters, urinary bladder, and bronchi (Crassousi, 1937; Einhorn, 1938). The drug is marketed in oral tablets containing 75 mgm each, the dose being one or two tablets two or three times daily. Trasentin is also supplied in ampules containing 75 mgm in 1.5 cc of solution. The single hypodermic dose is 50 to 75 mgm. Trasentin is not official and is not included in N.N.R.

Homatropine

The chemical structure of this synthetic alkaloid has been given (Table 24). Homatropine may be viewed pharmacologically as a weakened atropine because it is both less active and less toxic than atropine. For example, from five to 10 times more homatropine than atropine is required to block the effects of vagal impulses. The drug is used solely for its actions on the eye and is employed as a one or two per cent solution of its hydrobromide or hydrochloride salt, or in the form of gelatin lamellae. Homatropine mydriasis is brief in duration. Homatropine is thus preferable to atropine when an extended increase in intraocular pressure must be avoided. Also, the patient is not inconvenienced by prolonged disturbance of vision due to cycloplegia. Homatropine is ineffective, as a rule, for the production of cycloplegia in children. The drug has been employed as a mydriatic in combination with ephedrine, paredrine and benzedrine. Repeated administration of homatropine to the eyes will result in satisfactory and fairly transient paralysis of accommodation. This requires the use of three or four drops of a two per cent solution every 10 or 15 minutes for one or two hours. The effects subside in approximately 24 hours.

Homatropine Hydrobromide, U.S.P., B.P., is the only official preparation. It consists of colorless crystals or a white, crystalline powder, soluble in six parts of water.

Eumydrine

Eumydrine is a methyl nitrate salt of atropine (atropine-N-methyl nitrate) (Table 24). It is occasionally employed in a solution of 0.5 per cent as a mydriatic, being less potent and less persistent in action than atropine. The peripheral autonomic effects of the drug are qualitatively similar to those of atropine but are less marked. At one time eumydrine was employed to suppress sweating. It has also been used in the treatment of pyloric stenosis in infants (Dobbs, 1939). The drug is not official and is not included in N.N.R.

Eucatropine

This synthetic drug was introduced as *euphthalmine.* Its chemistry has been mentioned (Table 24). It is employed solely as a mydriatic and causes no paralysis of accommodation. The action of eucatropine on the pupil is rapid and brief in duration. Maximal dilatation occurs in 30 minutes, and the iris returns to normal in two or three hours. The drug is thus safe and convenient to use and has no deleterious effect on intraocular pressure.

Eucatropine Hydrochloride, N.N.R., a white, odorless, water-soluble, granular powder, is administered as a five or 10 per cent solution, two or three drops being instilled into the eye, or tiny tablets of the alkaloid containing 1.5 mgm may be inserted directly in the conjunctival sac where solution in the tears is rapidly effected. The peripheral actions of eucatropine closely resemble but are weaker than those of atropine.

CHAPTER 26

AUTONOMIC BLOCKING AGENTS

II. DRUGS INHIBITING STRUCTURES INNERVATED BY ADRENERGIC NERVES

ERGOTAMINE AND ERGOTOXINE

Drugs which inhibit effector cells from responding to adrenergic nerve impulses or to epinephrine belong in the main to two classes. The first group is composed of two natural alkaloids found in ergot—*ergotoxine* and *ergotamine*. The second group consists of synthetic *dioxane derivatives.* In addition, a number of miscellaneous drugs also block the responses of sympathetically innervated structures. These include *yohimbine,* its diastereoisomer *corynanthine,* and *apocodeine.*

The history, chemical nature and general pharmacology of the ergot alkaloids are discussed elsewhere (page 654), and it is necessary to consider here only those features which pertain to their autonomic properties. The dioxane derivatives are mainly of academic interest and have not been widely employed in therapeutics. *Yohimbine,* an alkaloid obtained from a West African tree (*Yohimbéhé*), likewise has no valid therapeutic uses although at one time it was employed in hypertension and promoted as an aphrodisiac. *Corynanthine* also remains chiefly an experimental drug.

Mechanism of Action of Sympathetic Blocking Agents. Drugs which inhibit the responses to adrenergic nerve stimulation or to epinephrine act peripherally on effector cells. The details of this action have been discussed (page 340) in relation to the concepts of humoral transmission of nerve impulses. Ergotoxine and ergotamine prevent effector cells from responding both to adrenergic nerve impulses and to epinephrine. Hence these drugs are both *sympathicolytic* and *adrenolytic.* The chemical mediator (adrenine or sympathin) is still liberated in the ergotoxinized animal but effector cells no longer respond to it. Ergotoxine and ergotamine differ little from each other and are effective in preventing augmentative rather than inhibitory sympathetic responses. Indeed, after the administration of these alkaloids, epinephrine or sympathetic nerve stimulation may no longer cause a rise in blood pressure and may even produce a fall. This reversal of response is referred to as *epinephrine-reversal* by ergotoxine (page 403; Figure 40).

The dioxane derivatives differ from ergotoxine and ergotamine. The best known of these compounds is 2-piperidinomethyl-1,4-benzodioxan, commonly called *Fourneau 933* or *933F.* This drug is *adrenolytic* and not sympathicolytic, that is, it blocks the response of effector organs to epinephrine but not to adrenergic nerve impulses. In this respect, 933F is analogous to atropine. Closely related dioxanes, however, differ from 933F in having more ability to annul the responses to nerve stimulation, as for example, *883F* (2-diethylamino-ethyl-1,4-benzodioxan). The ability of the dioxanes to block transmission in autonomic ganglia in a manner similar to nicotine is apparently unrelated to their peripheral sympathicolytic or adrenolytic action on effector cells. Yohimbine is chiefly adrenolytic. There is some *in vitro* evidence that 933F may owe part of its blocking action to an ability to facilitate the destruction of epinephrine (Morison and Lissak, 1938).

ERGOTAMINE AND ERGOTOXINE

Preparations. *Ergotoxine ethanesulfonate,* although an official reference standard in the U.S.P. and widely used experimentally, is not easily obtainable in the United States. The closely allied alkaloid *ergotamine,* on the other hand, is readily available as the *tartrate* salt (Gynergen, N.N.R.). This is marketed in tablets (one mgm) for oral or sublingual administration and in solution in ampules (one cc containing 0.25, 0.5 or 1.0 mgm) for intravenous or hypodermic injection. The details of the preparations of ergot alkaloids are given on page 661. Their chemical structure is discussed on page 655.

Inasmuch as *ergotamine tartrate* and *ergotoxine ethanesulfonate* have practically the same pharmacological properties, discussion may be limited to ergotamine because of its wider use and the greater body of clinical information which has accumulated concerning it.

Clinical Properties of Ergotamine. The pharmacology of ergotamine is presented under ergot. This drug shares with other ergot alkaloids the ability to stimulate the smooth muscle of the uterus and blood vessels. Ergotamine depresses the receptive mechanism of organs innervated by adrenergic nerves. In human beings, however, ergotamine in therapeutic doses (0.5 mgm subcutaneously) manifests only slightly and irregularly this autonomic blocking effect. For example, ergotamine reversal of the rise in blood pressure caused by epinephrine cannot be demonstrated in man. In fact, when epinephrine is injected following ergotamine, the blood pressure may rise more than with epinephrine alone, probably due to the direct vascular constriction caused by the ergot alkaloid. On the other hand, the elevated metabolic rate and increase in blood sugar induced in man by one milligram of epinephrine are partially inhibited by ergotamine. The typical inhibition seen experimentally in laboratory animals after large doses of ergotamine is not elicitable clinically.

Although ergotamine is employed for a miscellaneous group of clinical syndromes, the mechanism of action involved cannot be explained satisfactorily. Clinical uses of ergotamine are described here for convenience of presentation, and it must not be assumed that benefit is due to inhibition of sympathetic responses.

Therapeutic Uses

Migraine. Ergotamine tartrate is a valuable agent for relieving migrainous headaches, having been introduced by Maier in 1926 for this purpose. The drug slowly gained favor until today it is viewed by a number of clinical investigators as a fairly specific agent for symptomatic therapy of migraine.

Mechanism of Action. Ergotamine is not a sedative or analgesic, and other forms of pain are not influenced. Its specificity for migraine is indicated by the fact that only occasionally are other types of headache relieved. Indeed, ergotamine may cause headache in normal persons (Lennox, Storch and Solomon, 1936). It has been suggested that migraine is due to vasospasm and that ergotamine may act to relax the involved meningeal or cerebral blood vessels by blocking the effects of sympathetic nerve impulses. The vasospastic etiology of migraine, however, has not been proved (Storch, 1937), and it is doubtful whether therapeutic doses of ergotamine exert autonomic blocking effects in man. Furthermore, ergonovine, which lacks a sympatholytic action, is moderately effective in migraine.

Attempts have been made to correlate the direct vascular constriction produced by ergotamine with its efficacy in migraine. In both normal and migrainous individuals, the drug causes an increase in cerebrospinal fluid pressure and cerebral blood flow. These effects are probably secondary to the rise which occurs in the systemic blood pressure, for both the systolic and diastolic levels are elevated and the pulse pressure and pulse rate are decreased. Other agents, such as epinephrine or inhalation of carbon dioxide, which cause similar or greater responses in cerebral blood flow, however, do not uniformly relieve headache. Clinical investigations on this subject do not lend support to the theory that migraine is accompanied by generalized cerebrovascular spasm or abnormalities of intracranial pressure (Lennox, Gibbs and Gibbs, 1935; Pool, Storch and Lennox, 1936).

The effect of ergotamine on arterial tone is also reflected in the marked decrease in pulsation of the temporal arteries which occurs after therapeutic doses in patients with attacks of migraine (Graham and Wolff, 1938; Wolff, 1938). The pulsation of the temporal artery is reduced by 40 to 50 per cent coincident with the ergotamine-induced relief of migraine. A parallel decline has been noted in the amplitude of the arterial pulsation and the intensity of the headache (Figure 46). On the basis of these findings, it has been suggested that migraine may be associated with an increased amplitude of pulsations of cranial arteries.

Dosage and Route of Administration. Subcutaneous or *intramuscular* injection is the usual method of administering ergotamine tartrate. The dose is 0.25 to 0.5 mgm, and this may be repeated if the migraine is not relieved or if it recurs. No more than one mgm should be given in 24 hours. Occasionally ergotamine may be given *intravenously,* but this route should be employed only by those who are thoroughly familiar with the use of the drug. The intravenous dose is usually 0.25 mgm and must not be more than 0.5 mgm. The latter amount is the maximum allowable in 24 hours.

Tablets of ergotamine may be given *sublingually,* the dose being three or four mgm given as soon as the headache starts. One or two mgm may be given hourly thereafter, if necessary, until a total of 10 mgm has been taken. The average initial dose for *oral* ingestion is four to five mgm, and two mgm may be swallowed each hour thereafter until not more than 11 mgm have been taken.

The smallest amount effective in relieving the headache should be employed. Overdosage is the chief cause of untoward effects from ergotamine. The therapeutic courses outlined should not be repeated within the same week. After the drug has been given, the patient should lie down in a quiet, dark room for at least two hours. The speed and thoroughness of the relief from pain are directly proportional to the promptness with which medication is started after the onset of an attack. The preferred time to administer ergotamine is during the prodromal stage. By giving the drug early, the dose may be decreased considerably. If the seizure has reached its peak, larger amounts of ergotamine are needed. Not only does the drug then require a longer time for effective action, but unpleasant side-effects from medication are more pronounced. When more than eight mgm of ergotamine are required by the oral route in order to obtain relief or if the headache is severe, it is better to resort to the subcutaneous injection of 0.5 mgm. Oral medication is less effective than parenteral but may be satisfactory for mild or incipient attacks of migraine. The reason for the large oral dose is that ergotamine is poorly absorbed from the intestinal tract.

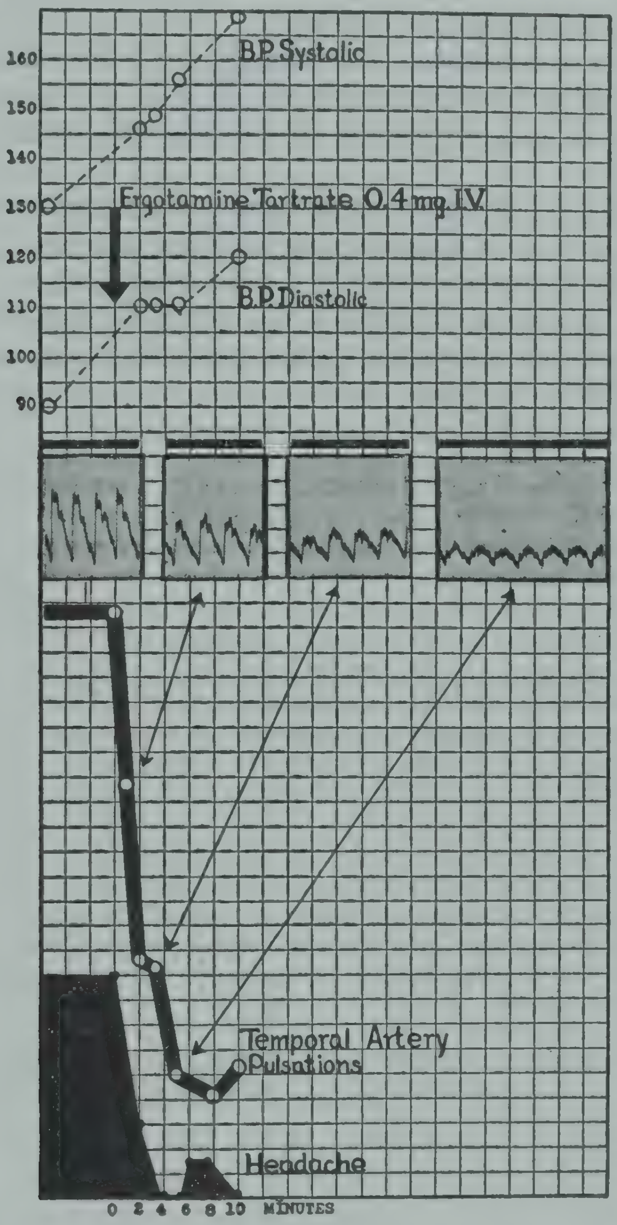

Figure 46. *Graphic representation of the response of migraine to ergotamine.*

The solid black line with open circles represents the average amplitude of pulsation of the temporal artery for any given minute before and after the intravenous administration of 0.4 mgm of ergotamine tartrate, the control amplitude being taken as 100%. Pulsation of the artery was measured by means of a tambour connected to a Frank capsule, the movements being photographically recorded. The individual pulsations are shown in the inserts of representative photographic records. The time line above the photographic records is in one-second intervals.

Note the rapid decline in intensity of headache (shown at bottom in solid black) after ergotamine, which is parallel both in time and degree with the decline in amplitude of pulsation of the temporal artery. The blood pressure rise seen here is not a constant feature of ergotamine therapy of migraine. Relief of headache is attributed to constriction of cranial vessels by the drug and consequent reduction in amplitude of their pulsations. (After Graham and Wolff, 1938. Courtesy of the *Archives of Neurology and Psychiatry.*)

Efficacy. The consensus of clinical opinion is that ergotamine is effective in the vast majority of cases (Lennox and Storch, 1935; O'Sullivan, 1936; Storch, 1938). Approximately 90 per cent of all patients or all attacks are relieved. The specificity of ergotamine for migraine is indicated by the fact that only 15 per cent of non-migrainous headaches are aborted. Relief is often dramatic. After parenteral injection of ergotamine, the headache may disappear in 15 minutes, but two hours or more may be required. Oral medication is much slower in bringing relief, averaging five hours, and it may fail in severe attacks. Continued use of the alkaloid does not result in diminished efficacy in subsequent attacks, provided adequate dosage is employed. The drug is not a cure and does not decrease the frequency of migraine headaches. Tolerance does not develop to ergotamine. The drug is not used to prevent attacks due to the danger of ergotism from continued medication.

Ergonovine in Migraine. Ergonovine, a newer alkaloid of ergot (page 658), is only moderately effective in migraine, terminating the headache in 37 per cent of 78 cases reported by Lennox (1938) and affording partial relief in 40 per cent. It has the advantages, however, that it is relatively more selective than ergotamine when given orally and that untoward gastro-intestinal symptoms are not so pronounced. Patients in whom ergonovine provides satisfactory surcease from attacks of migraine usually prefer this alkaloid to ergotamine.

Other Uses. The *obstetrical use* of ergotamine is given on page 667. The alkaloid has been tried in patients with *thyrotoxicosis* on the basis that many symptoms of the disease may be related to overactivity of the sympathetic nervous system. Clinical results have been disappointing, and furthermore a relatively large number of accidents from ergotamine have been reported in this group of patients. The drug has been used to relieve the generalized *itching* which occurs in jaundice, cirrhosis of the liver, leukemia, Hodgkin's disease, etc. The mechanism of the antipruritic action is unknown. The suggestion that the drug acts on sensory nerve endings seems improbable. Although relief is occasionally striking, ergotamine should be employed cautiously, if at all, for this purpose. Especially should it be avoided if the itching is due to hepatic disease.

Ergotamine has been suggested for the therapy of a variety of disorders without sufficient evidence for its efficacy or safety. These include certain psychoses, epilepsy, hypertension, paroxysmal tachycardia and tabetic cord-bladders. In none of these cases is the drug of value. The occasional success obtained with ergotamine in postural hypotension is probably related to the direct vascular (pressor) action of the alkaloid. The necessity for continued medication and the occurrence of unpleasant or toxic side-effects limit the usefulness of ergotamine in this syndrome. Ephedrine and related drugs are much safer and more serviceable.

Complications. A number of untoward effects may be noted from ergotamine therapy. These are especially likely to occur if large or frequent doses are employed or if the alkaloid is administered in the face of definite contraindications. Storch (1938) reviews 42 "accidents" reported in the literature. Twenty-three of the accidents occurred in obstetrical cases, and 11 in hyperthyroid patients. Gangrene occurred in 21 instances and there were eight deaths. Storch estimates that ill effects follow ergotamine in only 0.01 per cent of the cases in which the alkaloid is used. He calls attention to the fact that when ergotamine is prescribed in correct dosage in the absence of contraindications, it is a safe and useful drug and that no serious complications have been reported from its use in the migraine syndrome.

Ergotamine is capable of producing all the symptoms of ergotism. These are described elsewhere (page 660). Certain unpleasant effects, however, are seen with sufficient frequency during ergotamine therapy of migraine to deserve special mention here. Nausea and vomiting occur in a large number of patients, particularly after oral administration of ergotamine. Atropine sulfate (0.5 mgm subcutaneously) often relieves these gastro-intestinal effects. Weakness in the legs is common, and muscle pains in the extremities, which occasionally are quite severe, may occur. The intravenous injection of calcium gluconate (10 cc of a 10 per cent solution) may be used to relieve these pains, if they do not respond to massage and exercise. Numbness and tingling of the fingers and toes are other reminders of the ergotism which this alkaloid may cause. Precordial distress and pain suggestive of angina pectoris have also been noted, as well as transient attacks of tachycardia or bradycardia. Localized edema and itching may occur rarely in certain sensitive patients. Most of the effects enumerated are not alarming and do not require cessation of ergotamine therapy unless organic pathological conditions underlying the symptoms are demonstrable.

Contraindications. Sepsis is a definite contraindication to ergotamine therapy because pre-existing infection has been present in a number of cases in which ergotamine has caused gangrene. The drug should not be used in patients with vascular disease, such as syphilitic arteritis, marked arteriosclerosis, coronary artery disease, thrombophlebitis, and Raynaud's and Buerger's syndromes. Diseases of the liver or kidney are also contraindications. Serious accidents have been reported from the use of ergotamine in patients with pruritus (Comfort and Erickson, 1939; Yater and Cahill, 1936), especially when it is secondary to hepatic disease. Although it is difficult to cause abortion with ergotamine, pregnancy constitutes an objection to its use. Fortunately, migraine often ceases with the onset of pregnancy.

CHAPTER 27

AUTONOMIC BLOCKING AGENTS

III. DRUGS INHIBITING AUTONOMIC GANGLIA AND SKELETAL MUSCLES

NICOTINE AND CURARE

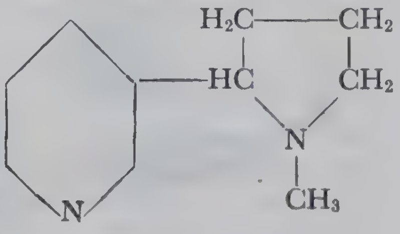
NICOTINE

Nicotine was discovered by Posselt and Reiman (1828) who isolated it from tobacco leaves. Orfila (1843) initiated the first pharmacological studies of the alkaloid and Langley and Dickinson (1889) described the actions of the drug on autonomic ganglia.

Using nicotine as a pharmacological tool, Langley (1889, *et seq.*) studied the sites of ganglionic synapse of autonomic efferent fibers, and in this manner greatly enlarged our knowledge of the physiology of the vegetative nervous system. He discovered that nicotinic paralysis of an autonomic ganglion prevents responses to preganglionic but not to postganglionic nerve stimulation. Therefore, if a fiber passes through a particular ganglion without synapsing, it is unaffected by application of nicotine to that ganglion. Conversely, if a nerve pathway is blocked by applying nicotine to a ganglion, it is presumptive evidence that a synapse occurs in that ganglion.

Although nicotine has no therapeutic uses, it is of great pharmacological interest. Furthermore, its high toxicity and presence in tobacco give nicotine a measure of medical importance. Preparations of nicotine are unofficial and available only for experimental purposes. The sulfate and salicylate salts as well as the liquid alkaloidal base are available.

Chemistry. Nicotine is one of the few liquid alkaloids. It is colorless, volatile, strongly alkaline in reaction, and on exposure to air it turns brown and acquires the odor of tobacco. The alkaloid is readily soluble in water and forms water-soluble salts. It is of interest to compare the structural formula of nicotine, which shows it to be a combination of a pyridine and a pyrollidine ring, with that of nicotinic acid and coramine.



Nicotine

Mechanism of Action. The autonomic action of nicotine consists of a primary transient stimulation and secondary more persistent depression of all sympathetic and parasympathetic ganglia. This is due to a direct action on ganglion cells, first to excite and then to paralyze them. During the stage of nicotinic stimulation, preganglionic impulses are more effective; during the stage of paralysis, preganglionic impulses are wholly ineffective. The effects of postganglionic stimulation, however, are quite unimpaired. Nicotine does not interfere with the release of acetylcholine in ganglia by impulses from the cholinergic preganglionic fibers, but renders the ganglion cells temporarily more sensitive and then more resistant to the chemical mediator. The effects of nicotine on skeletal muscle are similar to those on ganglia. In the stage of paralysis, nicotine thus manifests a curare-like action which is largely the basis for the toxic effect of the alkaloid on respiration. The relationship between synapses in autonomic ganglia and the junctions between motor nerve endings and skeletal muscles has been referred to (page 342) and provides a basis for understanding the curare-like action of nicotine. Curare, however, is much more specific for skeletal muscles than for ganglia, and the reverse is true for nicotine.

The expression "nicotinic action," which is applied to the action of choline esters on autonomic ganglia and skeletal muscles, arises from the similarity between the stimulatory effects of nicotine and acetylcholine on these structures (page 339).

In addition to its peripheral actions, nicotine affects the central nervous system. Here, again, the drug first stimulates and then paralyzes nerve cells.

Pharmacological Properties. The complex and often unpredictable changes which occur in the body after administration of nicotine are due not only to the several sites of action indicated above, but also to the fact that the alkaloid has stimulant and depressant phases of action. The ultimate response of any one structure may thus represent the algebraic summation of the different effects of nicotine. How complex these actions are may be understood by considering that the drug can speed the heart rate by the excitation of sympathetic or paralysis of parasympathetic cardiac ganglia, but can cause bradycardia by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. In addition, the effects of the drug on the medullary centers influence the heart rate, as do also the vascular reflexes resulting from changes in the blood vessels caused by nicotine. Finally, nicotine tends to produce a discharge of epinephrine from the adrenal medulla and this hormone accelerates the cardiac rate and raises the blood pressure.

Central Nervous System. Nicotine markedly stimulates the central nervous system. This is particularly evident for the respiratory, vasomotor and emetic centers of the medulla. Motor stimulation manifests itself in convulsions. The excitation of *respiration* is a particularly prominent action of nicotine and has been investigated especially by Heymans and associates (1931) and by Wright (1935). Although large doses of the drug stimulate breathing by a direct action on the medulla, smaller amounts appear to act reflexly on respiration through the excitation of the chemoreceptors of the carotid body.

Stimulation of the central nervous system is followed by depression, and death results from failure of the respiration. It appears, however, that before the medullary centers are completely paralyzed, the peripheral curariform effect of nicotine on skeletal muscle may incapacitate the muscles of respiration.

Peripheral Nervous System and Skeletal Muscles. The autonomic ganglionic actions of nicotine and its curare-like effect on skeletal muscles have been described. Nicotine blocks impulse conduction through nerve trunks only when applied directly to the nerve in high concentration.

Circulation. The effects of nicotine on the circulation are complex, as explained above, due to the multiple sites of action of the alkaloid. The *rate* of the heart is usually slowed at first, due especially to stimulation of the central vagal nuclei and cardiac vagal ganglia. Tachycardia is prominent later, or with larger doses, due to vagal ganglionic paralysis coinciding with stimulation of cardiac sympathetic ganglia. Various types of *arrhythmia* have been reported experimentally from large doses, and are due either to accentuated vagal or sympathetic nerve impulses or to a direct action of nicotine on the heart muscle. The *blood pressure* is elevated due to peripheral vasoconstriction resulting from central vasomotor and sympathetic ganglionic stimulation. In late stages of poisoning, the blood pressure falls due to vasomotor paralysis. The smaller *vessels* of the periphery, especially those of the skin, are constricted after nicotine, but may dilate when the sympathetic ganglionic stimulation passes into the stage of paralysis. The coronary vessels are said to share in the primary vasoconstriction.

Gastro-intestinal Tract. The nauseant effect of nicotine is well known to every one who remembers smoking his first cigar. Vomiting may also occur. These effects are mainly central in origin. Increased motor activity of the bowel, occasionally leading to diarrhea, may result from parasympathetic ganglionic stimulation. This can be blocked by atropine and is followed by a stage of inhibition of intestinal tone and motility.

Glandular Effects. Nicotine causes a primary stimulation of salivary and bronchial secretions which is followed by inhibition. The salivation caused by smoking is reflexly produced by the irritation of the smoke rather than by the nicotine because the subcutaneous injection of 0.4 mgm of the alkaloid (the amount that may be absorbed by smoking two cigarettes of common blend) does not stimulate saliva in smokers or nonsmokers (Schnedorf and Ivy, 1939). In dogs with gastric pouches, nicotine (0.2 to 1.0 mgm) given subcutaneously either has no effect on or causes a decrease of the acid production of the fasting stomach and the gastric response to a standard test meal (Schnedorf and Ivy, 1939). The secretion of milk in lactating women who smoke moderately is evidently not disturbed. The adrenal medulla is stimulated and then depressed by nicotine so that an increased output of epinephrine may accompany the stimulatory phase of action on sympathetic ganglia. The similarity between the adrenal medulla and autonomic ganglia in their responses to drugs has been discussed (page 332).

Absorption, Fate and Excretion. Nicotine is readily absorbed from the oral and gastro-intestinal mucosa and from the respiratory tract. Sufficient absorption may also occur from the skin to produce severe poisoning. Nicotine is detoxified to a large extent in the body, especially by the liver, and the remainder is excreted, mainly in the urine. Nicotine can be isolated in the form of its salts in the urine of tobacco smokers. Excretion is evidently slower than was formerly believed and three to four days are required after an individual has stopped smoking before most of the drug disappears from the urine. Nicotine appears to be the substance responsible for the marked pressor action of many specimens of urine, and the factor of smoking must be eliminated in studies on hypertension when human urines are examined for a "pressor principle" (Helmer, Kohlstaedt and Page, 1939).

Acute Nicotine Poisoning. Nicotine is one of the most toxic of all drugs and acts with a rapidity comparable to that of cyanide. Poisoning may occur from accidental ingestion of insecticide sprays in which nicotine is present as the effective agent. The lay use of tobacco infusions as enemas against intestinal parasites has resulted in death. Tobacco contains large amounts of the alkaloid and it is said that the nicotine content of one cigar approximates two lethal doses for man. The fatal dose for man is probably in the neighborhood of 60 mgm, although four mgm or less usually produce alarming symptoms in non-habituated individuals.

The onset of symptoms of severe, acute nicotine poisoning is rapid, and death may occur within a few minutes. Due to its alkalinity, the drug has a local caustic action in the mouth and stomach. Nausea and salivation quickly appear and are followed by abdominal pain, vomiting and severe diarrhea. Headache, dizziness, disturbed hearing and vision, mental confusion and marked weakness are experienced. Respiration is stimulated and the blood pressure may be elevated. The pupils are constricted but later become dilated. The pulse is usually slow at first and rapid terminally. Faintness and prostration ensue, the blood pressure falls, breathing is difficult, the pulse is weak, rapid and irregular, and collapse may be followed by terminal convulsions. Death results from respiratory failure due to paralysis of the muscles of respiration.

Therapy. Occasionally death is delayed sufficiently to allow treatment to be instituted. Primary attention should be paid to the failure of the respiration. This has been shown to be peripheral in locus and due to the curariform effect of the alkaloid on skeletal muscles. Inasmuch as nicotine is destroyed in the body with fair rapidity, death may be averted if the patient can be tided over the interval necessary for detoxication of the poison. Artificial respiration should therefore be instituted and continued as long as necessary or until the heart ceases to beat. Central respiratory stimulants are not indicated as a rule. The amount of nicotine necessary to cause central medullary paralysis is greater than that needed for peripheral interference with respiration (Franke and Thomas, 1936). Other therapy is purely symptomatic.

Tolerance. Tolerance develops to nicotine if the drug is repeatedly administered. This is quite evident in confirmed tobacco smokers who are unaffected by amounts of the alkaloid (eight mgm) which would cause marked symptoms in the tyro (Wahl, 1919). Cross-tolerance exists between nicotine and the closely related alkaloid lobeline.

Tobacco and Chronic Nicotine Poisoning

Tobacco is the dried leaf of *Nicotiana tabacum,* a plant indigenous to America but now grown in many parts of the world. The early settlers of the Western hemisphere learned the use of tobacco from the native Indians and introduced the tobacco habit into Europe. The use of tobacco for smoking, mastication or snuffing is indulged in by many millions of people throughout the world.

Chemical Composition of Tobacco. Nicotine is the most important pharmacological constituent of tobacco. The percentage of nicotine in tobacco varies considerably and may range from 0.5 to 8.0 per cent. Cigarette tobacco contains about 1.5 per cent (0.7 to 3.0 per cent) of nicotine and the smoke of the average cigarette may yield several "therapeutic" doses of nicotine (six to eight mgm). The smoke of 100 grams of cigar may contain from 150 to more than 400 mgm of nicotine. The amount of nicotine contained in tobacco smoke depends on many factors. Nicotine is present in the tobacco leaf as the salt of organic acids and is liberated by heat to the free form, which passes in varying degree into the smoke. Some of the alkaloid is burned but appreciable quantities, depending on the moisture, heat, rapidity of smoking, practice of inhalation, etc., gain access to the respiratory tract. Not all of this is absorbed because most of it is again exhaled or expectorated. Most commercial "denicotinized" tobaccos still contain significantly large amounts of the alkaloid.

In addition to nicotine, tobacco contains pyridine and other nitrogenous bases, volatile acids, tarry and phenolic substances, and especially furfural and acrolein. These chemicals undoubtedly contribute, along with free nicotine, to the irritation of the mucous membranes produced by tobacco and tobacco smoke (Bogen, 1936). Carbon monoxide and hydrocyanic acid are present in tobacco smoke in too low a concentration to be significant. Hygroscopic agents, such as glycerol, may add to the irritant effects of tobacco smoke, probably due to their yield of acrolein. Insecticidal sprays used on domestic tobacco plants may result in lead and arsenic contents of cigarettes far in excess of those limits allowed by law for foods (Ziedler and Wagner, 1937). Although lead and arsenic are potentially more harmful when volatilized and inhaled than when ingested orally, there is no absolute evidence as yet that toxic effects of tobacco are caused by the content of these metals. This question, however, deserves closer study in view of some questionable cases of arsenical dermatitis reported from the use of tobacco.

Chronic Effects of Tobacco. The acute effects of smoking in the novice are almost entirely due to the nicotine content of the tobacco. These have been described under nicotine intoxication. The symptoms, though unpleasant, are transitory and not alarming. The chronic use of tobacco by a large part of our population raises the problem of the *chronic toxicity* of nicotine. Many symptoms and diseases have been blamed at one time or another on the use of tobacco. Despite the vast amount of work done, it has not been established that the moderate use of this plant is deleterious to the overwhelming number of persons who indulge in the tobacco habit.

Nasopharyngeal and bronchial irritation may occur from tobacco smoking. This is due not only to the causticity of nicotine but, as has been stated, to the many other irritant constituents of the tobacco or its smoke. Mucosal epitheliomas may also result from the chronic irritation of tobacco and heat.

The effects of tobacco smoking on the motor and secretory activities of the *gastro-intestinal tract* have been carefully studied by Schnedorf and Ivy (1939) in chronic cigarette smokers, nonsmokers and smokers with peptic ulcer. They found that cigarette smoking reflexly stimulates *salivary secretion* by virtue of the irritant smoke and not because of the nicotine. The subcutaneous injection of 0.4 mgm of nicotine (the amount of alkaloid that may be absorbed by smoking two cigarettes) does not stimulate salivary flow. *Hunger contractions* of the stomach in man are reflexly abolished by smoking and the inhibition caused by smoking one cigarette may last for 15 to 60 minutes. The gastric *emptying time* of a test meal is not significantly altered by tobacco smoking in chronic smokers, but the gastric acidity may be reduced. In smokers with peptic ulcers, neither the rate of emptying nor acidity of the gastric contents is influenced by cigarette smoking. The experimental data are summarized in Table 27. The volume and acidity of the continuous fasting gastric secretion were also studied by Schnedorf and Ivy. In only one of 40 normal subjects were the volume and acidity enhanced; in 17, no significant alteration occurred and in 22 an appreciable decrease took place. In only one of 20 patients with peptic ulcer (a nonsmoker) was the acidity of the basal gastric secretion augmented; in eight, no significant change occurred, and in 11 subjects a decrease was noted.

These results offer no basis for the opinion held by many clinicians that cigarette smoking is harmful to patients with gastric or duodenal ulcer. The gastro-intestinal com-

* Saliva was not swallowed. A bouillon test meal with three crackers was used. Three or four cigarettes were smoked in one hour.

† Two showed a slight but significant retention; the acidity was significantly diminished in four.

‡ In one a significant retention occurred with smoking. In no instance was the rate of evacuation significantly lessened.

plaints sometimes caused by the use of tobacco may be secondary to cardiovascular disturbances. Unless it can be shown definitely in a particular patient with peptic ulcer that the use of tobacco is harmful, it is not necessary to proscribe smoking. The chronic user of tobacco experiences a certain pleasure and euphoria which may facilitate the digestive processes. Patients with ulcer, however, should be warned not to tax their tolerance for tobacco by overindulgence.

Schnedorf and Ivy also examined the claims that smoking augments the motor activity of the colon and that the cigarette indulged in after breakfast by many individuals to promote defecation has a pharmacological basis. They found in a systematic experimental study that smoking tended to increase the motor activity of the colon. It is possible that certain patients with colitis or irritability of the colon may benefit from restriction of the use of tobacco.

Considerable attention has been focused on the effects of tobacco on the *cardiovascular system.* In certain patients, the excessive use of tobacco may cause premature systoles and in an occasional person paroxysmal attacks of auricular tachycardia may be traced to smoking. In some individuals, tobacco smoking may produce an inversion of the T wave (Graybiel, Starr and White, 1938). There is no proof that the use of tobacco causes arteriosclerosis or results in angina pectoris (White and Sharker, 1934). In a patient who already has coronary sclerosis and angina pectoris, however, it is conceivable that overindulgence in tobacco may be a factor in precipitation of anginal attacks. This can be determined only by individual study of each patient and does not justify the indiscriminate interdicting of tobacco in persons with angina pectoris. The use of tobacco apparently plays no rôle in initiating *coronary thrombosis* (Master and coworkers, 1937).

The use of tobacco has long been suspected of being etiologically related to *Buerger's disease,* but the exact connection is far from clear. More than 90 per cent of all patients with thromboangiitis obliterans are smokers. Some authorities even claim that no instances of typical and unquestionable Buerger's disease have occurred in nonsmokers. The disease is apparently less severe and more amenable to therapy in those patients who give up smoking early and completely, at least so far as is indicated by the incidence of amputations (Horton, 1938; Silbert, 1938). Although nicotine is known to produce vasospastic phenomena, this fact does not prove that tobacco is the causative agent rather than an important contributory factor in the disease. Most clinicians are of the opinion that a patient with Buerger's disease should stop smoking completely, and that the continuance of the use of tobacco will tend to make the symptoms worse. In a large series of cases, Silbert (1938) observed no recurrence of the syndrome, once arrested by treatment, unless the patient resumed smoking. The rôle of tobacco in vasospasm and in the etiology of thromboangiitis obliterans has been reviewed by Moyer and Maddock (1940).

Tobacco amblyopia is a relatively rare complication of the tobacco habit. It is usually characterized by retrobulbar neuritis and if untreated may proceed to optic atrophy and permanent visual injury. Complete cessation of the use of tobacco is indicated in tobacco amblyopia, and vasodilators such as nitrites and choline esters, especially mecholyl, should be employed in therapy (Orr, 1936; Duggan, 1937). The evidence strongly suggests that spasticity of retinal vessels induced by nicotine provides the underlying basis for this syndrome.

The smoking of tobacco under controlled conditions of a standard smoking test is known to produce *peripheral vasoconstriction,* especially in the skin, in the vast majority of persons, regardless of whether they are healthy or suffering from vascular disease, and independently of the length of time tobacco has been used. The vasoconstriction is accompanied by a marked fall in skin temperature (Hines and Roth, 1938). The majority of individuals also respond to cigarette smoking with a rise in both *systolic and diastolic blood pressure,* and the rise is more marked in those who have essential hypertension. Excessive elevation of blood pressure induced by tobacco is noted especially in those persons who have inherently hyper-reactive vascular systems, as measured by the cold pressor test (Herrel and Cusick, 1938; Hines and Roth, 1938). The extent of these blood pressure changes can be seen in Table 28, compiled by Hines and Roth. This evidence, however, does not indicate that tobacco must not be used by hypertensive patients or by those with peripheral vascular disease (except Buerger's). Each patient should be studied to determine whether a moderate amount of smoking is harmful in his case.

Experimental results in animals do not indicate that the chronic use of nicotine causes vascular degeneration (Thienes and Butt, 1938), nor do reasonable amounts of the alkaloid affect general health or growth (Behrend and Thienes, 1932). Pearl (1938) investigated the effect of tobacco smoking on the length of life of nearly 7000 white males. While heavy smoking definitely impaired life duration, mild smoking only slightly decreased life expectancy. Should the conclusions of Pearl's study be substantiated (Short, Johnson and Ley, 1939), one would still have to weigh the pleasures derived from tobacco against the possibility that the life span may be decreased in a given case. Pearl noted that after the age of 70 the differences between the groups practically disappear, and suggests that those "who survive to 70 or thereabouts are such tough and resistant specimens that thereafter tobacco does them no further measurable harm as a group."

Table 28

RESPONSE OF BLOOD PRESSURE TO STANDARD SMOKING TEST AND COLD PRESSOR TEST

Classification of Subjects	Number	Mean Change in Blood Pressure, Mm. of Mercury					
		smoking test		control test*		cold test	
		Systolic	Diastolic	Systolic	Diastolic	Systolic	Diastolic
Normal blood pressure	30	21.1	13.0	4.2	−1.0		
Normal reactors to cold test......	20	17.2	7.6	2.8	−2.1	13.6	9.5
Hyper-reactors to cold test......	10	29.6	17.4	9.3	1.6	33.2	25.0
Essential hypertension	56	31.5	18.4	10.6	5.6	44.5	37.7
Smokers..........	45	40.9	23.0				
Nonsmokers.......	11	26.0	9.3				

* Puffing unlighted cigarette.
Hines and Roth, 1938.

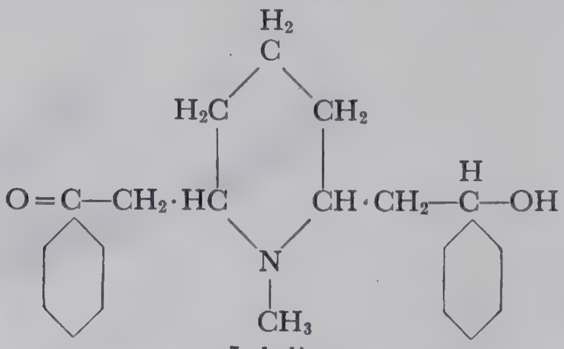
In *summary,* it may be stated that each patient must be studied carefully in an attempt to decide whether in his case tobacco is producing chronic intoxication. Although tobacco is contraindicated in Buerger's disease and in nicotine amblyopia, no generalities can be stated regarding the deleterious effects of smoking on patients with other disease syndromes. It is unfair and often unnecessary to request one to give up smoking, unless the evidence is of a much more convincing nature than that usually advanced.

The tobacco habit is not particularly easy to break. Although Mark Twain is recorded as saying that to cease smoking was the easiest thing he ever did, he hastened to add that he ought to know because he had done it a thousand times. The abstinence symptoms are mainly psychic (craving, restlessness, etc.) and do not have the profound constitutional basis as do those occurring in narcotic addicts. Often it is necessary only to decrease the amount of tobacco used or the degree of inhalation rather than to interdict smoking completely. The use of lobeline in tobacco withdrawal is discussed under that alkaloid.

LOBELIA

Lobelia, N.F., B.P. (Indian tobacco), is obtained from the dried leaves of an herb, *Lobelia inflata.* It was used in American medicine in the 19th century as an emetic, nauseant, expectorant and antiasthmatic. An alkaloid, *lobeline,* is the chief constituent of lobelia, and it was first obtained in crystalline form by Wieland in 1915 and named "alpha-lobeline."

Chemistry. The structural formula of lobeline is as follows:



Lobeline

Lobeline is usually available as the sulfate salt. The other alkaloids of lobelia are similar to lobeline in action but are weaker. The *tincture of lobelia* (N.F., B.P.) and *fluidextract of lobelia* (N.F.) are also available.

Pharmacological Properties. Lobeline has essentially the same actions in the body as nicotine. Indeed, animals tolerant to nicotine show cross-tolerance to lobeline. The drug stimulates the *central nervous system* and this effect is especially evident for the medullary, respiratory, and vomiting mechanisms. Central vagal stimulation may result in bradycardia, hypotension and bronchial constriction. Like nicotine, the alkaloid stimulates the chemoreceptors in the carotid body and thus reflexly increases respiratory rate and depth (Heymans and associates, 1931).

The *ganglionic actions* of lobeline consist of a primary stimulation followed by depression. The drug also has a curare-like action on *skeletal muscle*. The *cardiovascular* effects of lobeline are complicated and essentially similar to those of nicotine. Conduction disturbances occur due to a direct action of the alkaloid on the myocardium. The drug also causes a discharge of epinephrine from the adrenal medulla.

Preparations. Both alpha-lobeline and lobeline sulfate are marketed but neither preparation is official or Council-accepted. The alleged superiority of alpha-lobeline as a respiratory stimulant over other lobeline preparations has not been substantiated. The drug has been administered orally and parenterally.

Therapeutic Uses. Lobelia and its galenical preparations are obsolete in modern medicine. Lobeline, however, has been used as a *respiratory stimulant,* and has been given extensive trial in resuscitation of the new-born and in cases of poisoning by central depressant drugs. The hypodermic dose for adults is from three to 10 mgm. The efficacy of the alkaloid as a respiratory stimulant and analeptic, however, is rather capricious and variable. At best, the salutary effects of lobeline are brief in duration. Medullary excitation often involves the emetic center, and the action on the central vagal nuclei may result in a fall in blood pressure and slowing of the heart rate. The dose necessary to produce respiratory stimulation varies greatly from patient to patient and with the condition being treated. Brief benefit may be followed by even more pronounced depression. Indeed, improvement may fail to appear. A fall in blood pressure is likely to occur especially when the subject is deeply narcotized. The early enthusiastic clinical reports on the value of lobeline as a respiratory stimulant and analeptic have not been substantiated and the drug is too dangerous and uncertain in action to warrant its employment in preference to more effective and safe therapeutic agents.

Because of the cross-tolerance which exists between nicotine and lobeline, the latter drug has been proposed for the *control of the tobacco habit.* It is taken orally in capsules containing eight mgm of lobeline sulfate, the dose being repeated as necessary during the day to control acute withdrawal symptoms. A week of gradually decreasing use of the drug is said to be generally sufficient (Dorsey, 1936). Wright and Littauer (1937), however, report that lobeline sulfate employed to break the tobacco habit may cause faintness, vomiting, epigastric pain and anorexia, and that most patients express a desire to give up smoking without the help of the substituted drug.

CURARE

Curare is an important pharmacological tool for laboratory investigations, but as yet it has no well-established therapeutic uses. The drug is an extract of the barks of several species of *Strychnos* plants and is employed by the South American Indians as an arrow poison. Synonyms for this extract include *curara, urari,* and *woorari.* Despite the fact that curare was first brought to England by Sir Walter Raleigh in the latter part of the 16th century, systematic investigation of the drug was first undertaken in 1850 by Pelouze and Claude Bernard. Although curarine was isolated in crystalline form by Preyer in 1864, even today much remains to be learned concerning the chemical nature and pharmacological actions of this powerful alkaloid. After prolonged and intimate study of the South American Indian methods of preparing curare, Mr. Richard C. Gill has been able to learn the technic of manufacture of the drug by the natives and has brought to the United States a sufficient amount of authentic curare for extensive experimental investigation (Gill, 1940).

Chemical Composition. Curare is obtained by brewing the stems, roots, bark and leaves of several species of *Strychncs.* Commercial curare is a brownish or black shiny, resinoid mass, soluble in cold water and dilute alcohol. Reliable curare extracts are difficult to obtain and the commercial supplies are often unsatisfactory. The active principles in curare are alkaloids, but their chemical structures remain unknown. The alkaloids differ in each variety of curare and these varieties are usually designated by the containers in which they are supplied to importers. Thus, there are three types of curare—that in bamboo tubes is known as *tubocurare;* that in gourds is called *calabash curare* (from *Strychnos toxifera*); and that supplied in earthenware jars is named *pot curare.*

Tubocurare is the most common form of extract but its source is undetermined. It contains two alkaloids, *tubocurarine* which possesses the main characteristics of the crude drug, and *curine* which is much weaker. Calabash curare is the most desirable extract and yields *curarine,* an extremely potent alkaloid similar to tubocurarine, and related chemically to strychnine. Pot curare contains three alkaloids, only one of which, *protocurarine,* has typical curariform properties.

The chemical basis for curariform activity of drugs is not known. At present, it appears that this property is independent of detailed chemical structure. Many onium salts, for example, possess curare-like potency in addition to nicotinic and muscarinic activity (Ing, 1936). These include quaternary ammonium salts, simple phosphonium, arsonium, stibonium, sulfonium and iodonium salts, and the methochlorides of several alkaloids, such as quinine methochloride (Harvey, 1940).

Mechanism of Action. Curare is an autonomic blocking agent which acts mainly on skeletal muscles and to a lesser degree on autonomic ganglia. It prevents these structures from responding either to nerve impulses or to injected acetylcholine. Brown and coworkers (1936) have shown, however, that small doses of curarine block the response of skeletal muscle to injected acetylcholine more readily than the response to a motor nerve volley. In this respect, the autonomic blocking action of curare on skeletal muscle resembles that of atropine on certain smooth muscles (page 340). This inhibition of response is due to a direct action on the cell. The release of acetylcholine by impulses in preganglionic autonomic fibers to ganglia and by somatic motor nerve impulses to voluntary muscles is not prevented by curare but the response to the chemical mediator is blocked. The selective blocking of ganglionic transmission and of neuromuscular junctions is not due to a paralytic action of curare because the involved cells are still capable of responding to other forms of stimuli. Thus curarized ganglion cells can be discharged by potassium salts and skeletal muscle fibers can be made to contract by direct electrical stimulation. Curare also exhibits its typical effects on structures whose nerves are completely degenerated. The choline esters, physostigmine and prostigmine are pharmacological antagonists to curare in their stimulatory phase of action on ganglia and skeletal muscles.

The action of curare does not extend to structures innervated by postganglionic autonomic fibers, and thus smooth muscle and gland cells are not affected directly. By acting on skeletal muscles and ganglia, curare blocks the "nicotinic" actions of acetylcholine. Curare shares its specific autonomic properties with nicotine but differs from this latter alkaloid in three important respects. Curare has a much less pronounced effect on ganglia than has nicotine; it lacks the initial stimulatory phase of the action of nicotine; and finally curare does not have the ability specifically to stimulate respiration as does nicotine.

Pharmacological Properties. The action of curare on skeletal muscle is the basis for the outstanding effects of the alkaloid in the mammalian body. The peripheral locus of this action was first described by Claude Bernard in his classical investigations which have become the basis for the experiment on drug localization performed today by medical students in the pharmacological laboratory. If the hind leg of a frog is ligatured in a manner which deprives the limb of its circulation but allows the sciatic nerve to remain free, the injection of curare into the ventral lymph sac produces typical effects in all parts of the frog except in the ligatured limb. In this limb, electrical stimulation of the sciatic nerve produces typical muscular contraction whereas the opposite limb is unresponsive to nerve stimulation. It is thus clear that curare does not act centrally but must reach the periphery before it can exert its action. Further localization is accomplished by showing that the curarized muscle is electrically excitable when stimulated directly and that the sciatic nerve, soaked in a solution of curare, is still capable of carrying impulses. This places the site of action at the motor end-plate or neuromuscular junction.

Curare also blocks transmission of impulses in autonomic ganglia but this property is not as marked as with nicotine. The ultimate effects of this action on any particular organ depend upon whether the sympathetic or parasympathetic ganglia are more markedly affected. Ordinarily, death from paralysis of the respiratory muscles occurs before the ganglionic action is fully developed.

Curare stimulates the central nervous system. Strychnine-like convulsions are seen after the use of some samples of curare, and picrotoxin-like spasms after others. Ordinarily, however, convulsions are masked by the peripheral muscular depression.

Curare Poisoning. A curarized muscle first shows fatigue and weakness, and as poisoning continues it becomes totally flaccid and inexcitable. An animal, poisoned by this alkaloid, ultimately lies perfectly helpless and dies from asphyxia when the muscles of respiration are involved. The muscles of the fingers, toes, eyes and ears are affected first, then those of the limbs, neck and trunk and finally those of the diaphragm. Asphyxial convulsions do not occur because of the inability of the muscles to contract. Cardiac failure results from anoxia following the respiratory arrest, and not from a direct toxic action of curare on the heart. Consciousness and sensibility are retained until the end. Life can be saved by artificial respiration because curare is fairly rapidly destroyed and excreted by the organism. Recovery of muscles occurs in the reverse order to that of their paralysis and thus the diaphragm and intercostal muscles are first to recover their function.

The intravenous injection of curare in man (Bennett, 1940) results in immediate onset of effects. First, there is a feeling of heaviness of the eyelids, followed by bilateral ptosis, slight nystagmus, strabismus, and diplopia. The neck muscles are soon affected and the subject is unable to raise his head; facial expression is quickly lost, speech is slow, and the throat and jaw muscles then become flaccid. The spinal muscles are next involved and lastly there occurs complete paralysis of the arms and legs. The order of involvement of the skeletal muscles by curare is the same as that which occurs in a patient with progressive myasthenia gravis. After intramuscular injection, the effects of curare require 15 minutes to become evident.

Absorption, Fate and Excretion. Although the South American Indian may kill his game with blow darts poisoned with curare, the meat of the kill can be eaten with impunity. Evidently, gastro-intestinal absorption of curare is sufficiently limited so that the processes of detoxication and excretion prevent a toxic level of curare from accumulating in the tissues. It is also possible that the drug may be destroyed in the intestinal tract. Small hypodermic doses of curare are therefore more effective than large amounts taken orally. Thus, the drug may be sucked from a wound without danger provided there is no extensive ulceration of the mouth or enteric tract. Curare is partly destroyed by the liver and the remainder is eliminated unchanged by the kidney. An otherwise harmless dose of the drug may become toxic in the presence of impaired renal function.

Clinical Uses. Curare and its alkaloids have no valid, well-established clinical uses. Sporadic attempts have been made to employ curarine in tetanus, strychnine poisoning and other convulsive states, as well as in neuromuscular syndromes characterized by increased muscular movement, tone or rigidity such as spastic paraplegia, dystonic athetosis and advanced parkinsonism. Aqueous or alcoholic extracts of curare have also been injected parenterally in doses sufficient to produce generalized muscular flaccidity in order to protect patients receiving convulsive (metrazol) shock therapy for schizophrenia from developing traumatic fractures (Bennett, 1940). A major difficulty in the use of curare is to obtain that degree of action which will just permit the desired decrease in skeletal muscle activity without interfering with respiration (*see* Cole, 1934; Mitchell, 1935; West, 1936).

The most favorable therapeutic results obtained thus far are those reported by Burman (1939, 1940) in 19 patients with *spastic paralysis* and in several cases of *dystonia musculorum deformans*. The dose of the curare employed was variable, and ranged from 10 to 40 mgm given intramuscularly to 22 to 25 mgm given intravenously. Although the drug appeared to be excreted rapidly (within two hours), the beneficial effect generally lasted one or two days, occasionally longer. Injections were therefore given three times weekly. Benefit was noticeable immediately after intravenous administration of the curare, and 20 to 30 minutes after intramuscular injection. Apparently only spastic muscles are affected by the doses of alkaloid employed, because normal muscles and respiratory movements remained unimpaired. Repeated therapy did not cause harmful effects and tolerance did not develop. Untoward symptoms observed with larger amounts than were needed to improve spasticity included dizziness, diplopia, weakness, ataxia, etc., but no difficulty in breathing was noted. The symptoms lasted only 15 to 30 minutes. The results seemed to indicate distinct improvement in spasm and plastic muscular rigidity. In dystonia musculorum deformans, a bedridden patient may be made to walk again. Burman also reported good results in *torticollis.* In an effort to find a curare substitute, *erythroidine hydrochloride,* derived from the seeds of *Erythrina corralloides,* was tried in five patients, in only two of whom satisfactory results were obtained owing to the small amount of drug available. Erythroidine seems to be more active, less toxic, safer, and more easily prepared and assayed than curare. The dose is larger than for curare. The interesting experiments of Burman deserve repetition, and their corroboration is greatly to be desired.

Curare is used in the laboratory to produce immobility of animals without central nervous system paralysis, but it does not produce anesthesia.

SECTION VI

CARDIOVASCULAR DRUGS

A large number of drugs have as their major pharmacological action the ability to stimulate or depress the heart, or to constrict or dilate the blood vessels. These agents will be considered in this section. Many additional drugs, however, which also markedly influence the cardiovascular system are described elsewhere in connection with their other important pharmacodynamic properties. This second group includes the xanthines, the central nervous system stimulants, parasympathomimetic and sympathomimetic drugs, the belladonna alkaloids, nicotine, the ergot alkaloids, thiamine, thyroid, posterior pituitary, carbon dioxide, and numerous other agents.

CHAPTER 28

DIGITALIS AND ALLIED CARDIAC GLYCOSIDES

Digitalis and certain closely allied drugs have in common a specific and powerful action on the myocardium which is unrivaled in value for the treatment of heart failure. These cardiac drugs are mainly found in a number of plants but are also present in the cutaneous secretions of certain toads. The preparations commonly employed are obtained from digitalis, strophanthus or squill. In the following discussion, the terms *digitalis principles, cardiac glycosides* and *digitalis bodies* are used to designate the entire group rather than digitalis alone. The description of the pharmacology and uses of digitalis applies to all related cardiac glycosides unless otherwise stated.

History. A large number of plant extracts containing cardiac glycosides have been used by natives in various parts of the world as arrow and ordeal poisons. Squill was known as a medicine to the ancient Egyptians and is mentioned in the Ebers Papyrus (*circa* 1500 B.C.). The Romans employed it as a diuretic, heart tonic, emetic and rat poison. Strophanthus was introduced into medicine by Sir Thomas Fraser (1890) who discovered its digitalis-like action while studying African arrow poisons. A drug which has been used for centuries by the Chinese is the dried skin of the common toad. It is called Ch'an Su and is recommended especially for toothache and bleeding of the gums. The latter use is interesting because it long preceded the demonstration that the toad skin contains a high percentage of epinephrine, a local hemostatic. Powdered toad skins were also commonly employed in the folk medicine of western countries for dropsy until replaced by digitalis.

Digitalis or foxglove was mentioned in 1250 in the writings of Welsh physicians. It was described botanically 300 years later by Fuchsius (1542) who gave it the name *Digitalis purpurea* because the flower was purple and resembled a finger. Foxglove was occasionally used internally or locally for a number of unrelated diseases ranging from epilepsy to skin ulcers.

In 1785, William Withering, master physician and botanist of Birmingham, England, published his famous book entitled, "An Account of the Foxglove and Some of its Medical Uses." Every physician who uses digitalis would do well to read this scholarly work because many of the common errors current in digitalis medication were clearly anticipated and warned against by Withering. He tells how he came to use foxglove, 10 years before he published his results, as follows, "In the year 1775, my opinion was asked concerning a family receipt for the cure of the dropsy. I was told that it had long been kept a secret by an old woman in Shropshire, who had sometimes made cures after the more regular practitioners had failed. I was informed also, that the effects produced were violent vomiting and purging; for the diuretic effects seem to have been overlooked. This medicine was composed of twenty or more different herbs; but it was not very difficult for one conversant in these subjects, to perceive, that the active herb could be no other than the Foxglove."

Withering was conversant with the fact that digitalis was effective only in certain forms of dropsy but apparently did not associate this with the cardiac actions of the drug. He recognized that the heart was affected, however, for he wrote that, "It has a power over the motion of the heart to a degree yet unobserved in any other medicine, and this power may be converted to salutary ends." Apparently John Ferriar in 1799 was the first to ascribe to digitalis a primary action on the heart and to relegate the diuretic effect to a secondary rôle.

Whereas Withering knew and recorded the benefits to be derived from the proper use of foxglove, his advice was not always heeded. During the 19th century, digitalis was used indiscriminately, often in toxic doses, for many disorders. During the early 20th century, as a result of the work of Cushny, Mackenzie, Lewis and others, the drug gradually came to be looked upon as a specific in the treatment of auricular fibrillation. Only within the last 20 years has it become firmly established that the main value of digitalis is in the therapy of congestive heart failure.

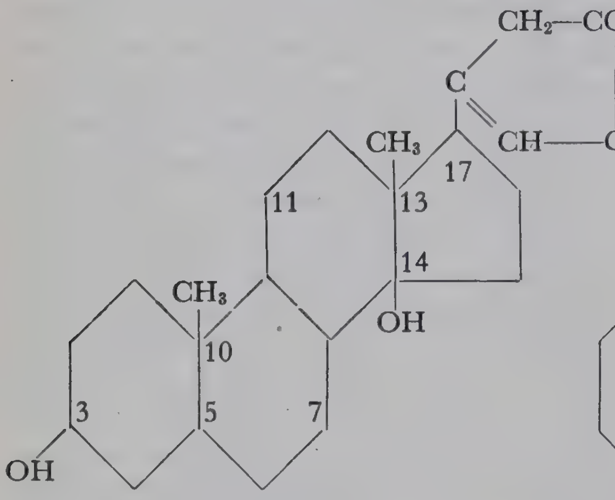
Source and Composition of the Digitalis Principles. Official digitalis is the dried leaf of the common and beautiful foxglove plant, *Digitalis purpurea,* a flowering biennial indigenous in many parts of the United States. The seeds and leaves of a number of other digitalis species also contain active cardiac principles. The official *strophanthus* is obtained from the seeds of the *Strophanthus kombé* or *hispidus,* members of the *Apocyanaceae* family. Other species of *Strophanthus* also contain active cardiac glycosides, and *ouabain* is derived from *Strophanthus gratus.* Official *squill,* the dried fleshy bulb of the "sea onion," comes from the *Urginea* (*Scilla*) *maritima,* a species of *Liliaceae.* Another member of this same family, *Convallaria majalis* (lily of the valley) was used for years in Russia for dropsy and yields a cardiac glycoside, *convallatoxin,* which is not now used clinically but possesses characteristic digitalis action. Belonging to the same family as the *Strophanthus* plant is a tropical tree, *Thevetia neriifolia* (yellow oleander) which produces a fruit known as the bestill or Malayan nut. The kernel of this nut yields the glycoside *thevetin* which has had some clinical trial (Arnold, Middleton and Chen, 1935). Many other plants contain cardiac glycosides but they are not listed here because their clinical value has not yet been fully established.

The active constituents of these cardiac drugs are *glycosides.* The cardiac glycosides of plant origin are usually found with *saponins.* The saponins are also glycosidic substances but lack specific effects on the heart. The best known saponins of the digitalis group are digitonin and gitonin. Although present in galenical preparations, the saponins exert no therapeutic activity but rather affect the solubility of the cardiac principles.

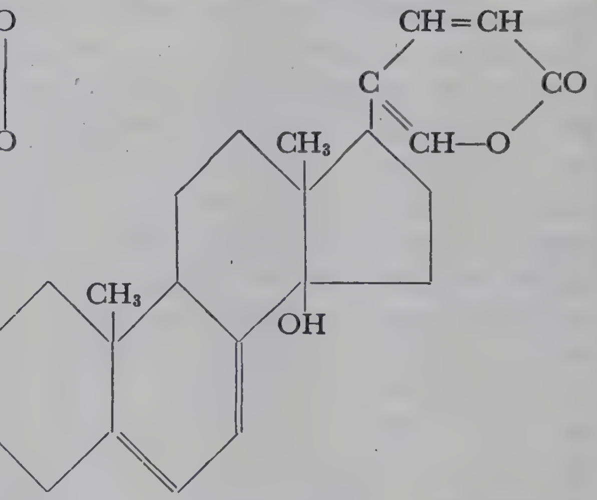
The numerous cardiac glycosides are composed of several constituent parts. Each glycoside represents the combination of an *aglycone* or *genin* with one or more molecules of sugar (Table 29). The pharmacological activity resides in the aglycone; but the particular sugars to which the aglycone is attached are thought to control water-solubility, cell penetrability, and persistence of cardiac action —hence, the therapeutic potency of the molecule. For example, the sugars are inactive when given alone, but when linked to aglycones the potency and toxicity of the latter are increased severalfold. The sugars are monosaccharides. Some of them are well known, such as glucose and rhamnose. Others, such as digitoxose and digitalose, are unusual pentose sugars which are found only in digitalis principles and are unlike any known sugars. The same sugar may occur in linkage with different aglycones. Likewise, different glycosides may yield on hydrolysis the same aglycone. For example, the glycosides of Canadian hemp (cymarin) and the seeds of *Strophanthus kombé* (k-strophanthus-β) both contain the aglycone *strophanthidin* (Table 29).

Chemical Nature of the Cardiac Aglycones. Rapid advances have been made in recent years in the complicated chemistry of the cardiac aglycones. Among the many contributions to this interesting field, the work of Jacobs, Windaus, Stoll, Fieser and their respective associates are outstanding and reference should be made to their publications for details. From the standpoint of the clinician, however, the swift development of this field of research has not yet resulted in information which is very helpful in therapeutics. For this reason, the following discussion is only a brief outline of the salient features.

The aglycones can be released from the cardiac glycosides either by acid or enzymatic hydrolysis. Their complex structure was but poorly understood until it was discovered that they are chemically related to the bile acids, cholesterol, sterols and sex hormones. The basic structure is a cyclopentenophenanthrene nucleus to which is attached a lactone ring. In addition, certain methyl, hydroxy and aldehyde groups are attached in specific positions, varying with the particular aglycone. The empiric formula, as a rule, is $C_{23}H_{34}O_{(4-8)}$. The structural formulas of two aglycones, *digitoxigenin* and *scillaridin-A,* are included here in order to demonstrate the characteristic features of these potent cardiac drugs.



Digitoxigenin



Scillaridin-A

Other important aglycones differ from those aforementioned in minor ways. For example, *gitoxigenin,* which is found in digitalis leaves with digitoxigenin, differs from the latter only in having an hydroxy group attached to C_{16}. *Strophanthidin* differs from digitoxigenin only by virtue of an hydroxy at C_5 and an aldehyde group at C_{10} instead of a methyl radicle. *Digoxigenin,* a third digitalis aglycone found in the *Digitalis lanata* species, has the same carbon skeleton but the position of a third hydroxy group has not been definitely assigned. The glycoside obtained from *Strophanthus gratus* is *ouabain,* a crystalline substance. The aglycone which it yields is called *ouabagenin,* the skeletal structure of which differs from digitoxigenin in having a CH_2OH group instead of CH_3 on C_{10}, and hydroxy groups on C_7 and C_{11} (Fieser and Newman, 1936). *Scillaren-A,* an important glycoside of *Squill,* yields the aglycone *scillaridin-A* which differs from the aglycones of the digitalis-strophanthus group in having an extra C atom. This carbon is in the lactone ring which therefore makes scillaridin-A the intermediate link between the cardiac principles and the bile acids.

The essential features of the sources and component chemical parts of the major cardiac glycosides are summarized in Table 29. A special indication for such a summary exists in the fact that the terminology employed in the literature is confusing and awkward, particularly because the names refer not to chemical structures but rather to botanical origins. Table 29 shows that the leaves of *D.*

TABLE 29

SOURCE AND COMPONENT CHEMICAL PARTS OF THE MAJOR CARDIAC GLYCOSIDES

SOURCE		GLYCOSIDE*	SUGAR	AGLYCONE
Digitalis purpurea	Leaves	deacetyldigilanid A −glucose = digitoxin	3 digitoxose	digitoxigenin
		deacetyldigilanid B −glucose = gitoxin	3 digitoxose	gitoxigenin
		gitalin	2 digitoxose	gitaligenin
	Seeds	digitalin**	glucose and digitalose	dianhydrogitoxigenin (digitaligenin)
Digitalis lanata	Leaves	digilanid A $-\begin{cases}\text{glucose}\\ \text{acetyl}\end{cases}$ = digitoxin	3 digitoxose	digitoxigenin
		digilanid B $-\begin{cases}\text{glucose}\\ \text{acetyl}\end{cases}$ = gitoxin	3 digitoxose	gitoxigenin
		digilanid C $-\begin{cases}\text{glucose}\\ \text{acetyl}\end{cases}$ = digoxin	3 digitoxose	digoxigenin
Strophanthus S. sarmentosus		sarmentocymarin	sarmentose	sarmentogenin
S. gratus		ouabain	rhamnose	ouabagenin
S. kombé		k-strophanthin-β (strophanthin)	glucose and cymarose	strophanthidin
		k-strophanthoside	2 mol. glucose and cymarose	strophanthidin
Apocyanum (Canadian hemp)		cymarin	cymarose	strophanthidin
Squill		scillaren A	glucose and rhamnose	scillaridin A
Thevetia neriifolia (Be-still nut)		thevetin	glucose (2 mol.) and digitalose (?)	thevetigenin

Compiled from data presented by Fieser (1937) and Stoll (1937, 1939).

* The digilanids and deacetyldigilanids are "native" glycosides as they are supposed to occur in the plant.

** Not the commercial "digitalin."

purpurea and *D. lanata* yield the glycosides digitoxin and gitoxin, but that each species in addition contains a glycoside not possessed by the other. Stoll (1937) showed that these glycosides exist in the plants as precursors, called native glycosides. In the case of *lanata* leaves the precursors are termed digilanids A, B and C, which upon mild alkaline hydrolysis (loss of acetyl group) and enzymatic hydrolysis (loss of glucose) yield the glycosides digitoxin, gitoxin and digoxin respectively. Further acid hydrolysis splits off the peculiar pentose sugars mentioned above and yields the aglycones. In *purpurea* leaves, however, the precursors or native glycosides contain no acetyl groups and no analogue of digilanid C.

They are known as deacetyldigilanids A and B, which upon enzymatic hydrolysis yield digitoxin and gitoxin. In addition, this species has the glycoside *gitalin* which is not present in the lanata leaf.

Relationship Between Chemical Structure and Cardiac Action. In the discussion of the opium alkaloids of the phenanthrene series, it was pointed out in detail how slight alterations in the morphine molecule resulted in specific and marked changes in pharmacological actions. In regard to the cardiac aglycones, however, no such discrete correlation exists. So far as is now known, all the aglycones mentioned above produce the same type of cardiac effect. It is possible, therefore, only to suggest the features of the molecular structure which are essential for this activity.

Practically all the cardiac aglycones have a secondary OH group in the C_3 position characteristic of the sterids, but a particular stereochemical configuration at C_3 is thought necessary for the cardiotonic effect. For example, the very weak action of *uzarin* is probably connected with the lack in this aglycone of the characteristic OH configuration in the C_3 position. The number and position of the other hydroxyls are probably unimportant except for determining solubility. The unsaturated lactone ring is absolutely essential for the myocardial effects of cardiac aglycones. Saturation of the ring destroys both potency and toxicity. Opening of the ring similarly abolishes pharmacological activity of the molecule. Whether the unsaturated lactone ring attached to other skeletons than the cyclopentophenanthrene nucleus would manifest cardiac activity remains to be demonstrated. The interested reader is referred to Jacobs (1933), Elderfeld (1935), Fieser (1937) and Stoll (1937) for details of the chemistry of the cardiac glycosides.

Cardiovascular Actions of Digitalis Principles

The main systemic effects of digitalis and allied cardiac drugs are manifested on the cardiovascular system. In addition, digitalis has some actions on the nervous system. An analysis of the actions of digitalis on the cardiovascular system is complicated by the multiple and interrelated functions controlling the circulation and also by the fact that digitalis elicits different responses in health and in disease. Another disturbing feature is that practically nothing is known of the basic mechanism whereby digitalis affects heart muscle. There is no question that cardiac muscle is much more sensitive to cardiac glycosides than are other muscles of the body. It also appears that the glycosides enter the cell protoplasm and are there split to release the active aglycones. How the latter cause such remarkable changes in muscular contraction is a mystery. The following description, therefore, is limited to observed facts rather than to the explanation of how digitalis causes the heart muscle to beat more forcibly. Wherever possible, these facts are taken from clinical investigations.

Action of Digitalis on Heart Muscle. The myocardial action of digitalis is its most important pharmacodynamic effect. Most of the changes in cardiovascular function caused by digitalis are an outgrowth of this direct action of the glycoside on heart muscle fiber. Other actions of digitalis are secondary and not indispensable. This concept of digitalis action is supported by the overwhelming number of clinical and laboratory investigations and it is no longer necessary to seek extracardiac or vagal actions of digitalis to account for the benefit derived from the drug in heart failure.

For many years, digitalis was looked upon as influencing the heart mainly through the slowing of cardiac rate which occurred under certain circumstances. This was due to the fact that digitalis was thought to be specific in the treatment of auricular fibrillation, in which it often dramatically slows the ventricular rate.

The slowing in rate was believed to be the basis for relief of symptoms. In this manner, the primary action of digitalis on the heart muscle was minimized or ignored and the drug was not recommended for heart failure with normal rhythm but rather reserved for arrhythmias with rapid heart rate. Starting perhaps with Wenckebach in 1910 and continuing with the clinical observations of Pratt (1918), Christian (1919), Luten (1924), Marvin (1926) and many others, the conviction grew and finally became firmly established that digitalis was chiefly effective in congestive heart failure regardless of cardiac rhythm, and that it brought relief not by virtue of cardiac slowing but rather by its direct action to increase the force of the myocardial contraction.

Effect on the Force of Systolic Contraction. Digitalis acts on the myocardium to increase the force of systolic contraction. This has been demonstrated directly on strips of heart muscle, in isolated mammalian hearts, in heart-lung preparations, in experiments of various types in intact animals, and indirectly in man. As long ago as 1855, Vulpian, who was the first to experiment with digitalis, noted that it caused a systolic contracture of the frog's heart. This fundamental observation is still the basis of the U.S.P. bio-assay of digitalis on frogs. Accurate mammalian experimentation on the direct myocardial effects of the digitalis bodies was initiated by Cushny (1897) and countless investigators have contributed to the literature on this subject. Details must be sought in special reviews (Robinson, 1923; Cohn and Stewart, 1924; Cushny, 1925; Weese, 1936; Luten, 1936). To skip almost 90 years of investigation and cite examples of the modern type of work, the results obtained by Cattell and Gold (1938) on the isolated papillary muscle of the cat may be mentioned. They stimulated the muscle at a constant rate and employed concentrations of ouabain and digitoxin compatible with therapeutic amounts in man. The drugs increased the systolic tension several-fold whether the muscle was contracting at optimal or at high diastolic tensions (short diastolic length). These results appear to prove that digitalis acts directly on heart muscle to increase the force of systolic contraction independently of other cardiac or extracardiac factors. Working with tortoise hearts, Kabat and Visscher (1939) obtained results in essential agreement with those of Cattell and Gold. The primary action of digitalis glycoside (K-strophanthosid) was to cause an increase in the work capacity of the heart muscle without associated changes in diastolic elasticity of the ventricular muscle (cardiac tonus).

When digitalis increases the force of contraction in the failing heart, the ventricle empties more completely. The heart is rendered capable of caring for an increased venous return, and if venous pressure is high due to congestive failure, this pressure is lowered toward normal. The diastolic filling may be increased, especially if the rate of the heart is slowed. Not only is the force of systole improved but the length of time in each cardiac cycle occupied by systole is shortened. This naturally allows more time for the heart muscle to rest and for the ventricle to fill. Auricular muscle is also directly stimulated by digitalis, especially if circus movement is not present.

Not only does digitalis increase the force of contraction but it apparently increases the mechanical efficiency of heart muscle. Animal experiments indicate that after digitalis the heart is able to do a given amount of work with less consumption of oxygen (Gremels, 1933; Peters and Visscher, 1936). This may be related to the fact that digitalis decreases the diastolic size of the heart, and it has been shown that for a given amount of work the oxygen need of the heart increases as the diastolic size of the heart increases.

The strengthened cardiac systole caused by digitalis affects markedly other properties of the heart beat, and influences other aspects of cardiovascular function now to be considered.

Heart Rate. The present conception of the action of digitalis minimizes the importance of cardiac slowing as a factor in the beneficial effect of the glycoside in heart failure. The overemphasis placed on the slowing of cardiac rate after digitalis obscured for years not only the major and direct action of the drug on the myocardium but also the main indication for its use, namely, cardiac decompensation.

In animals, digitalis can be shown definitely to decrease the rate of the heart. This action is mediated in large part through the vagus nerves because it is not so manifest after atropinization or vagotomy, and it is not prominent in isolated hearts. The manner in which the vagus is stimulated by digitalis is not completely clear. Earlier explanations held that the glycoside excited the medullary vagal nuclei. Other work indicates that the drug sensitizes the pacemaker of the heart to the normal vagal impulses. Heymans and his coworkers (1932), from cross-circulation experiments in animals, concluded that perfusion of the vagal centers with digitalis does not slow the heart but that characteristic bradycardia results when the drug has access to the region of the carotid body. They therefore believe that the carotico-aortic vasoreceptor system is stimulated by digitalis (through hypertension) to cause *reflex* vagal slowing of heart rate. It may be noted that the clinical investigations of Weiss and coworkers (1938) indicate that digitalis increases the excitability of the carotid sinus and enhances the tendency to arrhythmias and cardiac arrest in patients with hyperactive carotid sinus reflexes. *The most likely manner in which digitalis causes vagal slowing of the rapid heart rates seen in clinical heart failure is reflexly through restoration of cardiac compensation.*

Regardless of the fact that bradycardia occurs after digitalis in animals, *the question of importance is whether the therapeutic effects of digitalis in man are the result of digitalis-induced vagal slowing.* Congestive heart failure is often relieved in man by clinical doses of digitalis without evidence of cardiac slowing. Furthermore, if slowing does occur, benefit may be observed earlier than any change in rate. Again, when the rate is decreased by digitalis it is mainly in patients who have a tachycardia accompanying the heart failure. Even in auricular fibrillation where digitalis exerts its most prominent slowing of ventricular rate, the drug usually does not slow the ventricle unless heart failure exists. One must therefore conclude from these basic clinical observations that *digitalis may cause conspicuous improvement in heart failure without the intervention of primary cardiac slowing.* This conclusion is strengthened by the fact that changes in heart rate are insignificant and variable when full doses of digitalis are given to persons without cardiac failure.

The foregoing discussion is not intended to signify that slowing does not occur after digitalis but only that it is not a necessary or primary factor in the relief obtained. The mechanism of the decrease in ventricular rate by digitalis in patients with auricular fibrillation will be discussed later. In cases of failure with a sinus tachycardia, the glycoside also slows the heart rate. The inference cannot be drawn that the drug acts directly on the sinus mechanism to slow the rate. Tachycardia in heart failure is usually considered a compensatory response to maintain the circulation. As digitalis improves the circulation and relieves the failure by its myocardial action, the cause of the tachycardia is corrected and the heart rate is decreased. The normal factors adjusting and controlling heart rate are involved in this slowing which is largely reflex in nature. Slowing, therefore, results from reflex increase to normal in vagus tone and a corresponding decrease in cardiac sympathetic discharge.

It is fortunate that the quieting effect of digitalis on the rapid rate of failing hearts is accomplished through the basic mechanism of improved muscular ability of the heart (Luten, 1936). If the slowing produced by digitalis were a primary effect unrelated to the restoration of cardiac compensation, the result might be much less salutary. As Wiggers (1931) has aptly pointed out, "There is no medicinal agent by which a compensatory sinus tachycardia can easily be abolished; otherwise many a patient with serious heart disease would have been helped prematurely to his grave through kindly intentioned but misguided treatment."

Toxic doses of digitalis rather characteristically cause excessive slowing of the heart rate. This is due in part to a vagal effect but in larger part to a direct action of the glycoside on the pacemaker and conduction tissue. The details of this toxic type of slowing are presented in the section on digitalis poisoning.

Special Aspects of Digitalis Action on the Heart Rate. (1) *Effect on the Cardiac Pacemaker.* In patients with heart disease and normal sinus rhythm, digitalis in therapeutic amounts produces neither constant nor significant slowing of the heart rate. This is true whether the heart is compensated or in failure. In normal healthy individuals, full doses of the glycoside may cause some slowing of rate but this averages only about eight beats per minute. Therefore if therapeutic amounts of digitalis affect the sinoauricular node of man directly or through vagal stimulation, this action is not prominent. Even in patients with sinus tachycardia due to hyperthyroidism or infection, digitalis in full doses has little restraining action on the rate of pacemaker discharge. Toxic doses of digitalis, however, affect the sinoauricular node directly.

(2) *Effect on the Conduction System.* Conduction between the auricle and ventricle is slowed by clinical doses of digitalis and this may be reflected in an increased P-R interval in the electrocardiogram. The slowing of conduction occurs in normal as well as in decompensated hearts. The action of digitalis on conduction is partly vagal in origin but mainly a direct action of the drug on the conduction bundle. It must not be forgotten that the bundle of His is composed of muscle tissue which shares the same cardiotonic effect of digitalis as does the remainder of the myocardium. When cardiac muscle contracts more strongly, its refractory period is increased and its rate of conduction is decreased. Under certain circumstances, both these factors tend to impede auricular impulses from reaching the ventricle. When a normal sinus rhythm exists and the auricular impulses are neither numerous nor weak, they can all get through to excite the ventricle even though clinical doses of digitalis have somewhat delayed their passage. The A-V delay in itself, therefore, under these circumstances does not cause any change in cardiac rate. With toxic amounts of digitalis, however, degrees of A-V block may occur which so interfere with the transmission of auricular impulses that partial heart block or complete auriculoventricular dissociation may result.

(3) *Mechanism of Cardiac Slowing in Auricular Fibrillation.* Although therapeutic amounts of digitalis do not materially slow the rate of the heart with a normal sinus rhythm, the same dose of drug may have a pronounced effect on the ventricular rate in patients with auricular fibrillation. In this arrhythmia, the auricular impulses are quite weak and may number well over 500 per minute. A large number of these impulses are automatically blocked by the conduction system and never reach the ventricle because the A-V bundle cannot normally conduct more than 270 impulses per minute. Others arrive during the refractory

phase of the ventricle and consequently are ineffective. Nevertheless, altogether too many auricular impulses manage to reach the ventricle which thus beats rapidly and irregularly. When digitalis is given in full doses to patients with auricular fibrillation, the ventricular rate is often reduced to an optimal level (Figure 50). Both the vagal factor in slowing and the direct actions of digitalis on the conduction system cooperate to block auricular impulses (Gold and coworkers, 1939). As already stated, digitalis acts directly on the A-V conduction system to increase the refractory period and slow the rate of conduction. In addition, reflex vagal stimulation caused by digitalis affects the bundle of His to weaken impulse conduction. As a result, the number of impulses capable of passing over the bundle of His per minute is reduced appreciably. That the vagal component of the A-V depression is not indispensable is evident from the fact

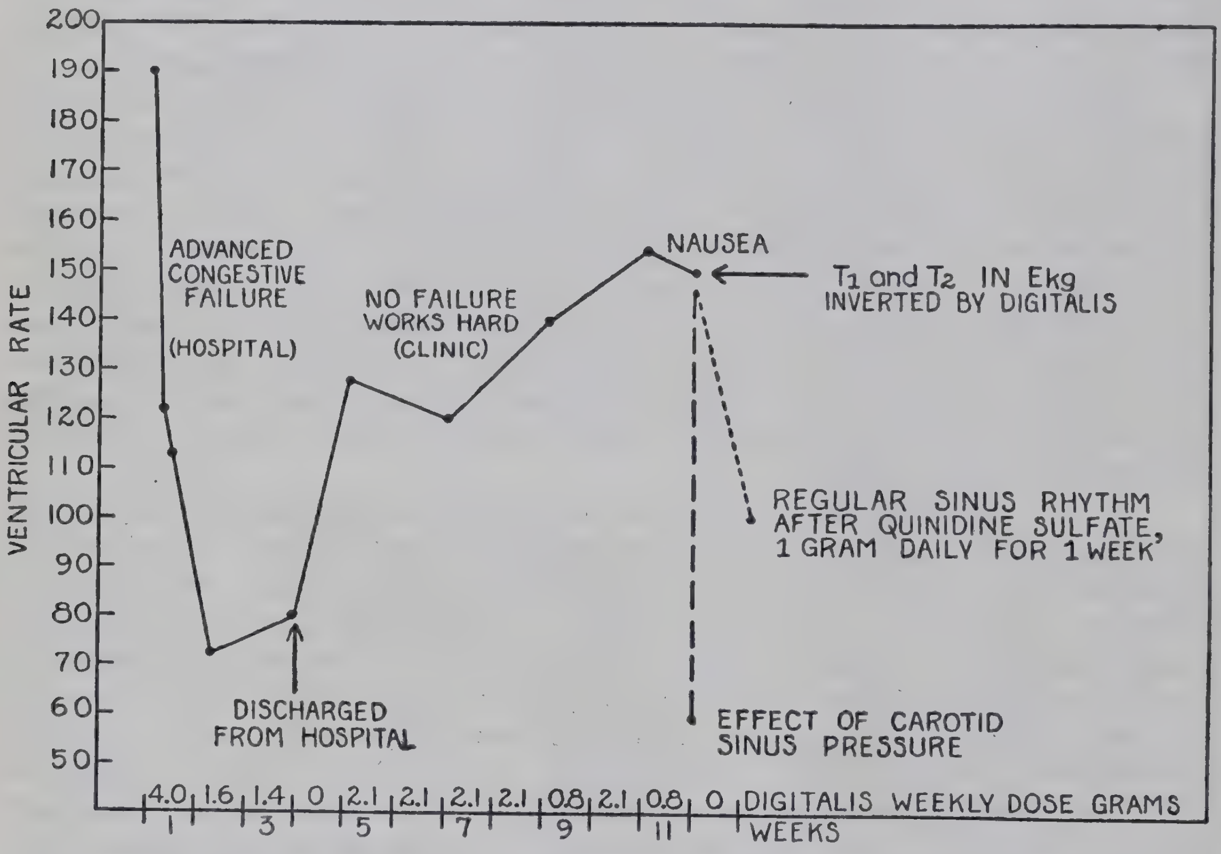


FIGURE 47. *Effect of digitalis on the tachycardia of heart failure and hyperthyroidism as compared with that of hyperthyroidism alone.*

Female, aged 52, weight 144 pounds. Diagnosis: Congestive heart failure and auricular fibrillation, on the basis of hyperthyroidism. The weekly dose of digitalis is indicated in grams along the abscissa and the ventricular rate on the ordinate. While confined in the hospital with advanced congestive cardiac failure requiring emergency measures (phlebotomy, oxygen), the patient responded to digitalis and rest in bed with a slowing of ventricular rate to 70. After discharge from the hospital, while working hard and manifesting no physical signs or symptoms of congestive failure, the patient's ventricular rate gradually increased due to the thyrotoxicosis. Tachycardia persisted in spite of adequate doses of digitalis.

It is clear that digitalis slowed the rapid ventricular rate in this case only when failure was present, by restoring a competent circulation through improved myocardial function. When failure was absent, digitalis had no effect on the tachycardia. That the heart would have been able to respond with slowing if digitalis had any primary and direct action on the vagus mechanism is indicated by the fact that carotid sinus pressure produced reflex vagal slowing from 150 down to 60 beats per minute, a degree of slowing unusual in patients with auricular fibrillation. Thus digitalis-induced slowing in patients with tachycardia due to heart failure is secondary to restoration of cardiac compensation. (After Gold, Kwit, Otto and Fox, 1939. Courtesy of the *Journal of Pharmacology and Experimental Therapeutics.*)

that slowing may still occur after full doses of atropine or after vagotomy. The importance of the increase in refractory phase of the junctional tissue itself as the mechanism by which digitalis slows the ventricle in auricular fibrillation is too often overlooked.

Gold and associates (1939) have analyzed the relative importance of the vagal and extravagal components of the digitalis-induced slowing of the ventricular rate in patients with auricular fibrillation. The slowing produced by small doses of digitalis could largely be attributed to vagal stimulation in that the cardiac rate could be increased by large doses of atropine. This vagal slowing was interpreted as being largely reflex in nature and due to restoration of myocardial compensation. After full doses of digitalis, however, atropine no longer was capable of increasing cardiac rate and the ventricular slowing was clearly due to extravagal actions of digitalis (Figure 47).

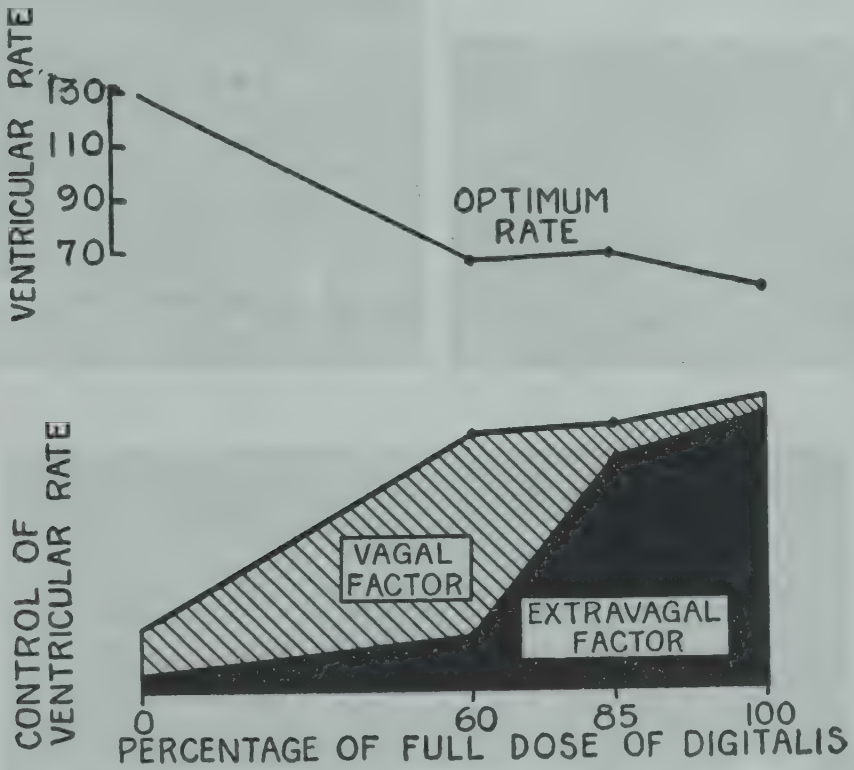

FIGURE 48. *Schematic representation of the mechanism by which digitalis slows the ventricular rate in patients with auricular fibrillation and congestive heart failure.*

The ventricular rate is shown in the upper portion of the figure, and the relative rôles in the cardiac slowing played by vagal and extravagal factors as the dose of digitalis is increased are indicated in the lower shaded and solid black sections, respectively. As small suboptimal doses of digitalis improve myocardial function, there is a resulting increase in the reflex activity of the vagus (vagal factor). Consequently, the ventricular rate is slowed. Atropine is effective in counteracting the reflex vagal activity and thus speeds the heart at this stage of digitalization. As the dose of digitalis is increased, the rate falls further and the direct action of the drug on the conduction system, *i.e.*, the extravagal factor, becomes more prominent. As the optimal rate is reached, the extravagal factor plays an increasingly dominant part in the control of the ventricular rate. Atropine does not annul the slowing due to the direct action of digitalis on conduction in heart muscle. Through a certain range, the ventricular rate remains constant and optimal despite the increasing depression of conduction caused by increasing amounts of digitalis. It is important to recognize that even though the ventricle is optimally slowed, one cannot predict from the degree of slowing exactly which mechanism, the vagal or extravagal, is dominant. The dominance of the extravagal factor is much to be desired as the more favorable for maintaining the optimum cardiac state in patients with auricular fibrillation and heart failure. (After Gold, Kwit, Otto and Fox, 1939. Courtesy of the *Journal of Pharmacology and Experimental Therapeutics.*)

Certain clinical observations make it appear that too much significance should not be attached to the digitalis effects on the junctional tissue as the mechanism by which digitalis slows the rate in clinical auricular fibrillation. In some cases of this arrhythmia, ventricular slowing may not occur at all after usual doses of digitalis. Evidently the factor deciding whether digitalis will decrease the ventricular rate in auricular fibrillation is the presence or absence of heart failure (Luten, 1936; Luten and Jeffreys, 1936). The direct action of digitalis on the decompensated myocardium is to strengthen the force of its contraction which automatically increases the refractory period of the muscle. The ventricle is thus rendered less excitable to the auricular impulses which manage to get through the junctional tissue from the auricle. Probably more important is the fact that the irritability of the myocardium is further reduced by the restoration of an adequate

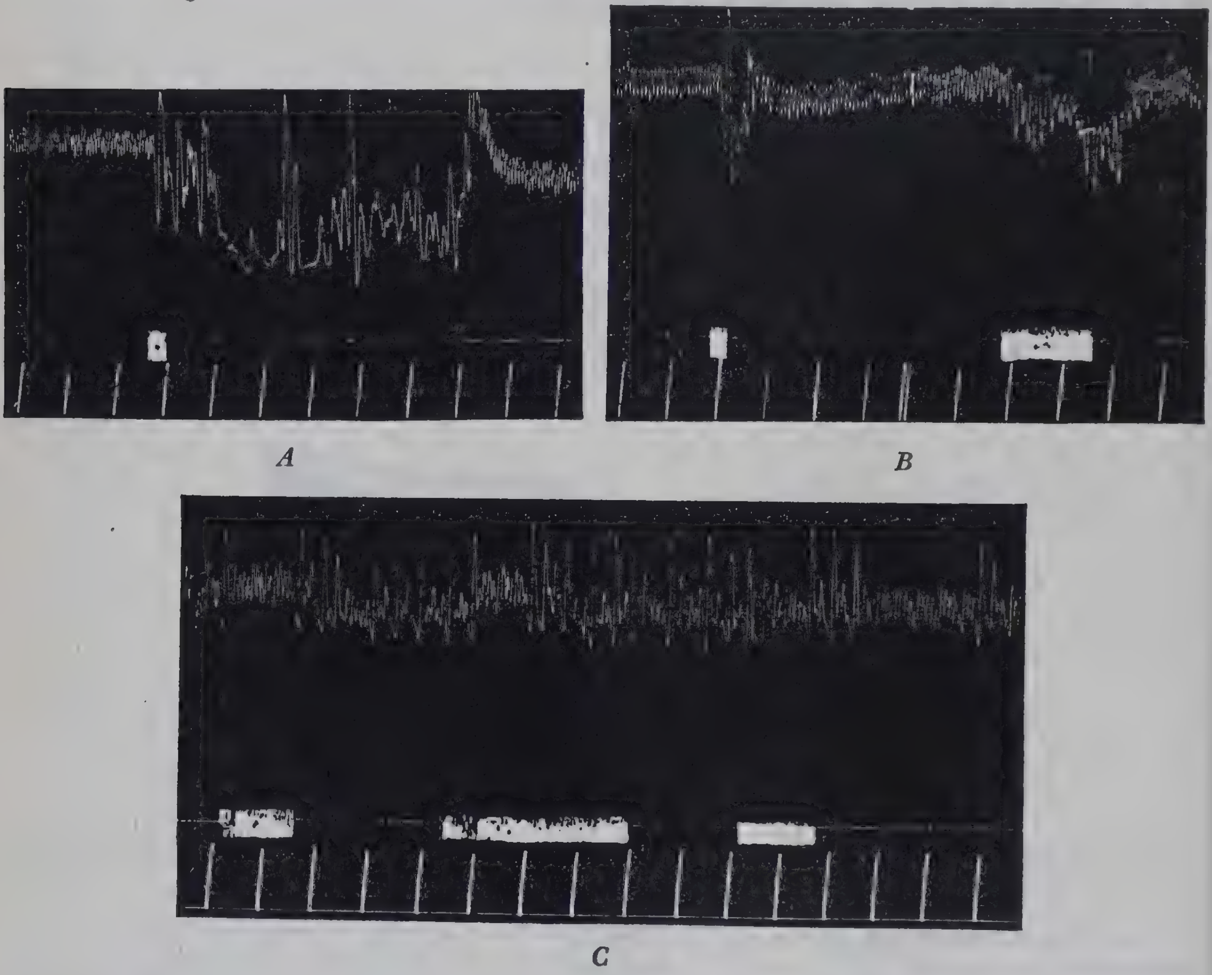

Figure 49. *The action of large doses of digitalis on auriculoventricular conduction in experimental auricular fibrillation.*

Dog, morphine-chloretone anesthesia, heart exposed, artificial respiration. Top line, carotid blood pressure; middle line, stimulation signal; bottom line, time in five second intervals. The auricles are periodically caused to fibrillate by means of an electric current delivered through Hirschfelder electrodes fastened to the auricle. The strength of the stimulus is not varied. *A.* Before digitalis, the effect of a short period of auricular fibrillation on the blood pressure and the rhythm of the ventricle. *B.* After 15 intravenous doses of digitalis, each corresponding to 0.25 cc of tincture of digitalis. *C.* After 27 doses. Note that the ventricle becomes less and less susceptible to the numerous auricular impulses arriving during the periods of fibrillation. At *C,* the ventricle is beating independently of the auricle (complete A-V dissociation) and a ventricular extrasystolic rhythm is present, caused by the very large doses of digitalis employed. The apparently slow ventricular rate appearing in *A* and *B* during periods of auricular fibrillation is due to a recording artefact resulting from the inertia of the mercury manometer. (After Barbour, 1932. Courtesy of Lea and Febiger.)

circulation and hence by an improvement in the coronary blood flow and nourishment of the heart muscle. A partially anoxic heart is known to be more irritable and hence will respond to stimuli which ordinarily are incapable of exciting it to contract. The tachycardia observed in many cases of auricular fibrillation with failure thus appears to be due to the failure itself. Tachycardia of an equal extent in auricular fibrillation not accompanied by failure, and due to a toxin increasing ventricular irritability, is not slowed by digitalis.

In *summary,* therefore it may be stated that ventricular slowing produced by digitalis in auricular fibrillation is the result of a dual mechanism. The more important is operative when heart failure is present in which case the drug restores compensation by improved ventricular power and thereby reduces the hyperexcitability of the ventricle to auricular impulses. Coincidentally, the vagal factor in the control of heart rate is restored. The second factor in slowing is the depressant action of digitalis on the conduction of auricular impulses through the junctional tissue. This latter factor appears to be secondary unless failure is absent or large doses of digitalis are employed (Figure 49).

In *auricular flutter,* digitalis acts similarly, but the effect of the glycoside on the junctional tissue is often intentionally sought by administering doses bordering on the toxic. In this arrhythmia, A-V block already exists and if this can be increased the ventricular rate falls appreciably. For example, if a 2:1 block is changed by digitalis to a 3:1 block, the ventricular rate is decreased by one-third. The direct action of large amounts of digitalis on the circus movement of the auricular muscle is also desired in this disorder, as explained later.

(4) *Slowing of the Heart Rate in Children.* It has been claimed that in children the vagus mechanism is especially susceptible to the action of digitalis and that cardiac slowing is therefore more important in the salutary effects of the glycoside in children than in adults. It appears, however, that no such special sensitivity exists. The misconception has arisen from the use of toxic amounts of digitalis in an attempt to obtain results, because the type of heart failure occurring in children is often refractory to digitalis. This refractoriness is probably explained by the fact that heart failure in children is usually due to an active carditis. Therapeutic benefit from the drug depends upon a direct cardiotonic action in children as well as in adults, and when improvement occurs it appears before and often without cardiac slowing.

Heart Size. Full doses of digitalis decrease the diastolic size of the heart. This is thought to be true for normal human hearts as well as those which are dilated in failure (Figure 50). Careful study of the surface area of the hearts of normal and decompensated individuals, as recorded by teleoroentgenograms, reveals a substantial decrease in heart size (Stewart and Cohn, 1932). In animals, both the normal heart and the heart with experimentally produced dilatation can be shown to decrease in diastolic size when full doses of digitalis are given (Cohn and Stewart, 1928).

The effect of digitalis on the diastolic size of the heart is undoubtedly related to the direct action of the drug on heart muscle. The finer mechanism of this alteration in diastolic volume, however, is disputed. There is much controversial literature on the question whether heart muscle has "diastolic tone." It is not known whether the myocardial fibers, during diastole, possess a degree of slight contraction (tonus) which offers resistance to the blood flowing into the ventricles and thus controls the degree to which the chambers fill. (See Johnson and Katz, 1937; Fishberg, 1938, and Best and Taylor, 1939, for discussions concerning tone in cardiac muscle.) The expression "diastolic tone," however, has come to be used rather loosely to signify diastolic size of the heart rather than myocardial tonus during diastole, as would be required in strict physiological parlance. For example, the decreased diastolic size of the heart occurring after digitalis is often considered to represent an increase in "diastolic tone." A decrease in diastolic volume, however, could also be due to a diminished venous return, a shortened duration of diastole, etc., quite independently of cardiac tonus. Indeed, Gold and Cattell (1938, 1939, 1940) and Kabat and Visscher (1939) hold that digitalis bodies are effective in heart failure not by increasing cardiac tone, as claimed by Stewart and Cohn and their associates, but by improving the strength of systolic contraction through a direct action on the myocardium. The experiments on papillary muscles and tortoise hearts referred to previously (page 505) indicate that digitalis enhances the force of systole without a decrease in diastolic length and throughout a wide range of diastolic lengths. It must be remembered, however, that the comparatively simple conditions existing in the experiments described cannot duplicate all the complex interrelated circulatory factors of the failing human heart in clinical cardiac decompensation. It is not profitable here further to pursue the question whether the decrease in diastolic length of the heart fibers (increase in "tone") is a primary action of digitalis or whether the increased systolic force of contraction alone can account for all the effects observed. The interested reader is referred to the critical review by Gold and Cattell (1940).

The important effects, especially on cardiac output and venous return, of the increased force of ventricular contraction and the decrease in diastolic heart size (increased "tone") may now be considered.

Cardiac Output. Many closely interrelated factors combine to determine cardiac output. These include heart rate, heart size, stroke volume, velocity of blood flow, peripheral resistance and venous return. The interpretation of the action of digitalis on cardiac output is therefore not a simple matter. In human beings or animals with normal hearts, cardiac output is definitely diminished by digitalis (Figure 50). In man, the decrease ranges between 20 and 35 per cent. This is due to the fact that the heart is decreased below its optimal size by the direct cardiotonic action of the drug. The capacity of the ventricular chamber is reduced and hence the stroke volume is lessened (Cohn and Stewart, 1928; Stewart and Cohn, 1932).

The fact that cardiac output in normal hearts is unfavorably influenced by digitalis led some workers to the conclusion that the drug was contraindicated in heart failure with normal rhythm. In failing hearts, however, cardiac output is not diminished by digitalis but is increased. This is demonstrable in man, intact animals or heart-lung preparations. As is the case in the normal heart, cardiac size is reduced but this change is from a dilated inefficient ventricle toward a more normal and efficient one. As a result of a more optimal diastolic size, stroke volume is increased, and systolic ejection of blood is more forceful and complete. The output increases regardless of the rhythm and independent of cardiac rate (Figure 50). It must be emphasized that the basic mechanism of digitalis action is the same in health and disease, namely to decrease the size of the ventricular chamber and increase the force of the ventricular contraction. The effect on cardiac output, however, depends on whether the chamber is originally normal or dilated. This interpretation has been advanced especially by Stewart and Cohn (1932).

The clinical studies of Stewart and collaborators (1938) have confirmed and advanced the aforementioned concepts of the effect of digitalis on cardiac output.

In 20 patients with congestive heart failure, showing decreased cardiac output and increased heart size, with normal rhythm or auricular fibrillation, digitalis caused the following changes: the cardiac output per minute and per beat was enhanced; the heart size was diminished; venous pressure fell if it was elevated; the velocity of blood flow was more rapid; and the work of the left ventricle per beat was increased and became more closely commensurate with heart size than before digitalis (Figure 50). The effects following digitalis in 22 patients with

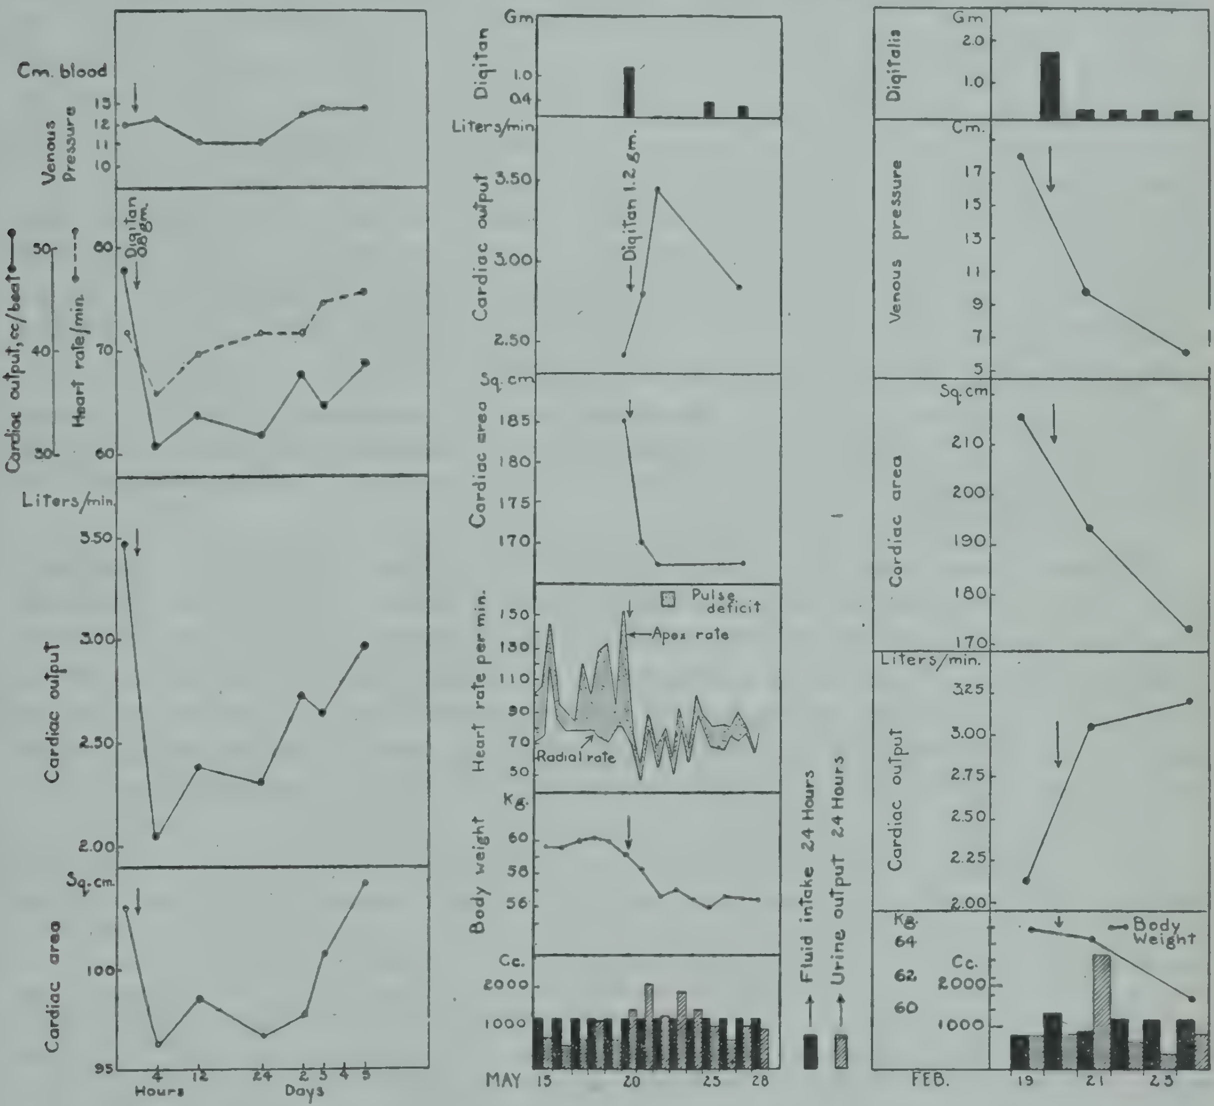

FIGURE 50. *The effect of digitalis in normal individuals and in patients with congestive heart failure.*

Left: Normal woman, aged 33, weight 52.5 kg. Digitan, 0.8 gram, decreased the cardiac area and this was accompanied by a fall in cardiac output per beat and per minute. The venous pressure and heart rate were not significantly altered. The slow return to normal of the cardiac area was associated with an increase in cardiac output.

Center: Woman, aged 51, congestive heart failure (fourth attack), auricular fibrillation, premature ventricular contractions, pulse deficit and edema. Digitan, 1.2 grams, produced diuresis, decrease in body weight, diminution in pulse deficit and ventricular rate, and a decrease in cardiac area accompanied by an increase in cardiac output. Effects were maximal within 48 hours.

Right: Man, aged 32, rheumatic heart disease, congestive heart failure, normal sinus mechanism. Digitalis, 1.7 grams produced diuresis, fall in body weight, return of elevated venous pressure to normal, and a decrease in cardiac area associated with an increased cardiac output.

Contrast the effects of digitalis on the cardiac size and output of the normal and decompensated heart. (After Stewart and Cohn, 1932, and Stewart, Deitrick, Crane and Wheeler, 1938. Courtesy of the *Journal of Clinical Investigation* and the *Archives of Internal Medicine*.)

compensated organic heart disease (no congestive failure) and with normal rhythm or auricular fibrillation were quite variable and unpredictable. Some of the patients responded like those with normal hearts, that is, showed a decrease in heart size and diminished cardiac output. Other patients reacted like those with congestive heart failure, that is, showed a decrease in heart size and an increase in cardiac output. Still other patients showed no alteration in heart size or cardiac output. In all instances, however, a decrease in cardiac output was always associated with a decrease in heart size; conversely, where the output was not affected, cardiac size was not altered. The conclusion drawn by Stewart and associates is that digitalis decreases heart size in heart failure and thus increases cardiac output. It does this by making the heart more efficient as a pump both in respect to its size and to the strength of contraction. Also, digitalis increases the work accomplished by the heart per beat, regardless of the ultimate effect on cardiac output, and regardless of the preexisting rhythm. The work of the heart thus becomes more nearly appropriate for the size of the organ. It is evident that Stewart and Cohn and their associates place more stress on the effect of digitalis to increase heart "tone" in contrast to the view of Gold and Cattell who emphasize the effect to increase the force of systolic contraction.

Evidence exists that digitalis produces an *increase in circulatory velocity* in patients with heart failure. This also strongly suggests that stroke volume is increased, because the rate of blood flow is enhanced independently of a change in cardiac rate or in the caliber of the peripheral vascular bed.

Venous Pressure. In the presence of increased venous pressure due to congestive heart failure, digitalis decreases the venous pressure. A fall of pressure from 20 cm of water to five cm within 24 hours is not unusual (Figure 50). This decrease in venous congestion is undoubtedly secondary to the improvement which occurs in the circulation and especially to the increased cardiac output. In normal patients or in those with isolated left ventricular failure, the systemic venous pressure is not elevated and digitalis has no significant effect on it (Figure 50).

Some competent workers, however, maintain that the primary action of digitalis is to lower the venous pressure and by this means remove the venous congestion of the failing heart and allow it to recover its efficiency. Evidence in support of this interpretation has been obtained especially in experiments on the dog (Dock and Tainter, 1930; Katz and collaborators, 1938). It is claimed that the site of action of therapeutic doses is on the peripheral vessels, in particular on those of the liver. Digitalis is said to constrict the smooth muscle in the hepatic vein, pool the blood in the liver and portal system, relieve the right side of the heart of the overdistention imposed by venous congestion, and in this manner improve cardiac function. Only toxic doses of the glycoside are admitted to be capable of action directly on the heart, and then only deleteriously so far as cardiac output and efficiency are concerned. Indeed, Katz and coworkers (1938), from experiments on the isolated dog's heart, claim that digitalis has no direct effect on the contractile power or mechanical efficiency of the myocardium either in the "physiological" or failing state. Supporters of the peripheral vascular site of action of digitalis believe that the drug acts favorably in congestive heart failure by storing blood in the splanchnic area, thus reducing circulating blood volume and venous pressure, that is, by performing a "bloodless venesection." This view stresses the importance of venous pressure in heart failure and assumes that digitalis acts on the hepatic veins of man as it does in the dog.

There are, however, many observations against this interpretation. First, according to most observers, heart failure is the cause rather than the result of increased venous pressure. Secondly, the venous pressure in marked congestive failure is insufficient to be a factor in stretching of the right ventricle. Thirdly, in isolated left ventricular failure, digitalis causes restoration of compensation without significant change in venous pressure. Fourthly, digitalis causes a decrease in the size of the swollen liver in congestive failure rather than an increase which is necessitated by the above theory. Finally, the amount of smooth muscle in the hepatic veins of man is quite sparse and forms no distinct sphincter for a sluice mechanism as does the more abundant smooth muscle in the dog. A critical analysis of the "liver" hypothesis of the action of digitalis has been presented by Gold and Cattell (1940).

Circulatory Volume. For reasons not fully understood, congestive heart failure is accompanied by an increase in the circulating blood volume (Fishberg, 1938). Digitalis acts to decrease the blood volume and probably does so by restoring cardiac compensation and removing the causes underlying the original increase. In patients with normal hearts, however, digitalis may also cause a diminution in circulatory blood volume. The mechanism of this action awaits elucidation.

Blood Pressure. In animals, digitalis may produce a rise in blood pressure due especially to a direct action on the smooth muscle of blood vessels but also in part to central vasomotor stimulation. Amounts required to cause this rise are toxic and out of all proportion to those used in man. Doses in animals comparable to those used clinically exert no such vascular constriction. Therapeutic amounts of digitalis cause no constant or significant change in the blood pressure of normal human beings.

In patients with heart failure, the administration of digitalis causes variable changes in blood pressure. The pulse pressure may be increased due to a lowering of diastolic pressure. This lowering may be the result of a reduction of vasomotor tone, elevated by a relative anoxia. The systolic pressure may also fall somewhat, especially if its level was high as a result of overcompensation subsequent to the failure. Low systolic pressures due to decompensation are elevated toward normal as digitalis improves cardiac function. It is clear, therefore, that digitalis affects blood pressure only through its action on the heart and not by any significant effect on the blood vessels or vasomotor center. The former hesitancy regarding the use of digitalis in hypertensive patients has no basis in fact. Patients who have hypertension and isolated left ventricular failure are often greatly benefited by the glycoside.

Comparison of Responses to Digitalis in Health and Disease. The salient features of the foregoing discussion are summarized in Table 30 and in Figure 50 which compare the actions of full doses of digitalis in patients with normal hearts and in those with congestive heart failure.

TABLE 30

RESPONSES TO DIGITALIS IN HEALTH AND DISEASE

EFFECTS OF DIGITALIS ON	PATIENTS WITH NORMAL HEARTS	PATIENTS WITH HEART FAILURE
Ventricular rate	Slight decrease as a rule	Usually decreased if previously rapid
Blood pressure	No significant change	No uniform or marked effect. May be increased if low, decreased if high
Venous pressure	No significant change	Decreased if elevated
Cardiac size	Decreased below normal	Decreased toward normal
Cardiac minute volume output	Decreased	Increased
Velocity of blood flow	Increased or decreased	Increased as a rule
Circulating blood volume	Diminished (?)	Diminished
Symptoms	May experience lassitude, dyspnea, substernal pain, etc.	Relief of dyspnea, cyanosis, edema, ascites, etc.

Coronary Circulation. Divergent views exist as to the effect of digitalis on the coronary blood flow. Some workers believe that the coronary vessels are an exception to the statement that toxic doses are necessary to cause vascular constriction, and they report coronary vasoconstriction from therapeutic amounts (Gilbert and Fenn, 1932). This view has its supporters in the clinical field who contend that digitalis in patients with angina pectoris tends to increase the incidence of attacks of pain. The opinion has therefore gained ground in some quarters that digitalis is contraindicated in angina pectoris.

That the digitalis glycosides in experimental animals decrease coronary blood flow is by no means agreed upon and some investigators have found an increase after the drug (Bodo, 1928; Hochrein, 1932; Rein, 1933; Ginsberg, Stoland and Siler, 1938). Essex, Herrick and Visscher (1938) reexamined this question by using the thermostromuhr method to test the mean blood flow through the circumflex branch of the left coronary artery in trained intact dogs. They found that full subnauseating doses of the native glycosides of digitalis lanata (digilanids A, B and C) have no effect on coronary blood flow.

The occurrence of pain in digitalized patients with angina pectoris cannot be accepted as presumptive evidence either that digitalis was the cause of the pain or that the drug induced pain by producing coronary vasoconstriction. In a careful and extensive study of 120 selected patients with angina pectoris without decompensation, Gold and coworkers (1938) demonstrated that digitalis does not increase or decrease the incidence of anginal attacks and that even large doses rarely, if ever, produce effective constriction of the coronary arteries. It must be concluded, therefore, that clinical doses of digitalis have not been shown to affect deleteriously the coronary circulation in man. Indeed, the blood supply to the failing myocardium may be improved as a result of the restoration by digitalis of cardiac compensation.

Diuretic Action. Withering employed digitalis in cardiac dropsy and for many years the foxglove was considered a diuretic. In no sense, however, is digitalis a true diuretic and its effects on urine flow are manifested entirely through its action on the heart and the circulation. In normal persons or in patients with heart failure but without edema or serous effusions, no diuresis is noted after digitalis. In cases with anasarca due to causes other than congestive heart failure, the glycoside likewise causes no increase in urine output. Furthermore, when digitalis fails to restore cardiac compensation in patients with cardiac edema, diuresis fails to develop. It is thus irrational to expect the drug to improve renal function which is unimpaired by a faulty circulation or to remove accumulations of fluid not due to heart failure.

It is clear, therefore, that diuresis following digitalis is secondary to the relief of heart failure. The mobilization of edema fluid causes the diuresis and not vice versa. Experiments on heart-lung-kidney preparations designed to demonstrate a direct action of cardiac glycosides on renal tubular cells to inhibit water reabsorption and thus cause diuresis do not duplicate clinical conditions, and results obtained from such experiments cannot be accepted as evidence for an extracardiac diuretic action of digitalis.

Diuresis is often one of the first prominent manifestations of digitalis action in edematous patients with congestive heart failure (Figure 50). Urinary output may rise within 24 hours from 200 cc per day to three liters or more. The specific gravity of the urine falls, the concentration of chlorides increases, the albuminuria diminishes and the phenolsulphonphthalein output rises. The body weight falls even when the edema is occult, and reveals the diuretic response to the improvement in heart function.

The main cause of edema and serous effusion in congestive heart failure is the increase in hydrostatic pressure in the venous ends of capillaries, preventing the normal resorption of extracellular fluid. This is discussed in detail elsewhere (page 643). As heart failure is relieved and venous congestion reduced, the edema fluid is returned to the blood. The resulting hydremia can actually be detected by a fall in the specific gravity of the plasma which occurs before diuresis is evident, affording additional proof that mobilization of edema fluid is the cause and not the result of the diuresis. Renal function is also improved by the relief of vascular congestion in the kidney. The better appetite and improved gastro-intestinal absorption resulting from a return of cardiac compensation lead to an increase in the concentration of serum protein, which may be sufficiently low in congestive heart failure to contribute to the edema formation. Fluid shifts similar to those occurring in the tissues and systemic circulation, as a result of failure of the right ventricle, also take place in the lungs and pulmonary circulation as a result of insufficiency of the left ventricle. Thus, when digitalis improves the function of the left side of the heart, pulmonary venous pressure is lowered and the signs and symptoms of pulmonary edema, such as râles and dyspnea, disappear.

Despite the effect of digitalis in mobilizing edema fluid in congestive heart failure, roughly one-half of all patients require additional and specific measures to promote diuresis (Figures 68 and 70). These are discussed in the chapter on diuretics.

Electrocardiographic Effects. Digitalis produces characteristic electrocardiographic changes which are often important in determining whether a patient has been receiving digitalis within the previous two or three weeks. However, these changes cannot in themselves be used for the purpose of quantitatively estimating digitalis dosage. Furthermore, the effects of digitalis are often superimposed on the changes resulting from the basic cardiac disease. The electrocardiogram must be interpreted with this fact in mind.

Within two to four hours after large oral doses of digitalis, definite alterations may appear in the electrocardiogram. This illustrates that the drug can be depended upon to act quickly when given by mouth. The first changes are noted in the RS-T segment or in the T wave itself. The normally upright T wave may become diminished in amplitude, flat or inverted in one or more leads. The RS-T interval may also show depression (Figure 51). Either of these changes may occur alone or both may coincide. Digitalis may result in a depressed T wave in lead I with an elevated T wave in lead III or vice versa, especially in cases where

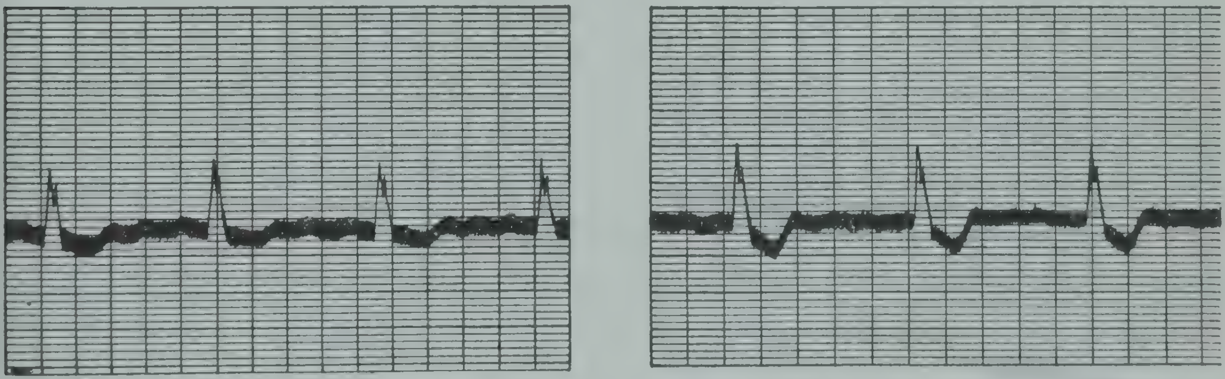

FIGURE 51. *Effect of digitalis on the RS-T segment and P-R interval.*

Female, aged 68, hypertensive arteriosclerotic heart disease. ECG: Lead 2. *Left:* P-R interval, 0.20 second. Early digitalis effect is seen in the sloping depression of the RS-T segment. *Right:* Tracing taken several days later shows considerably deeper depression of the RS-T segments in a manner typical of digitalis, and a marked increase in the P-R intervals to 0.30 second (incomplete A-V block). (Courtesy of Dr. A. J. Geiger, Yale University School of Medicine.)

there is a marked axis deviation with the T waves opposite in direction to that of the predominant portion of the Q-R-S complex. The T wave alterations may occasionally resemble those seen after coronary occlusion. This is particularly true in chest leads. Indeed, the alterations caused by digitalis in the form of the T waves and RS-T segments of the chest lead may simulate those resulting from coronary artery disease or recent coronary occlusion, and may cause confusion in the interpretation of the record if it is not known that the glycoside has been administered (Stewart and Watson, 1938). The changes in the RS-T interval and T wave are due to a direct action of digitalis on the heart muscle and are not affected or abolished by atropine.

The P-R interval may be prolonged by digitalis (Figure 51). This effect occurs somewhat later than those described above. The interval is rarely greater than 0.25 second. If it is greater than this after digitalis, preexisting disease of the conduction system may be assumed, and the degree of myocardial damage that this signifies is sufficiently great to reduce definitely the possibility of a good response to the drug. Atropine will abolish the lower grades of A-V block produced by digitalis signifying that they are in good measure due to the vagal effects of digitalis. Higher grades of block are not significantly affected by atropine and are due to a direct action of the glycoside on the conduction bundle.

The Q-T portion of the tracing is shortened by digitalis and reflects the fact that the drug lessens the duration of ventricular systole. Large doses may occasionally cause changes in the size and shape of the P wave and result in abnormal rhythms which are detectable in the electrocardiogram. Almost every type of tracing due to cardiac disorders, except intraventricular conduction defects, can be simulated by the effects of digitalis on the heart.

That the T wave changes usually occur before the P-R interval is prolonged indicates again that digitalis acts first and foremost on the heart muscle itself. The T wave alterations may require two to three weeks or longer to disappear after the drug is stopped. Experiments on cats illustrate the order of appearance of the electrocardiographic changes in relation to the percentage of the lethal intravenous dose of digitalis required to elicit them, as follows (Robinson and Wilson, 1918): T wave effects appear after 24 per cent of the lethal dose; P-R interval increased after 53 per cent; ectopic beats after 72 per cent; complete A-V dissociation after 80 per cent.

Symptoms and Signs of Digitalis Overdosage. The toxic effects of digitalis are largely extensions of the therapeutic actions of the drug. For this reason, a "nontoxic" digitalis does not exist. A preparation which will not cause digitalis poisoning when given in excess is also one which will not exert any therapeutic effect. This point is an important one to recall when the physician is appraising the claims made by pharmaceutical firms for their particular brands of digitalis, its purified fractions or substitutes. The use of digitalis carries with it the obligation to understand and recognize those toxic actions of the drug which call for cessation of therapy. Only in this way can successful results be obtained with digitalis.

Withering wrote, "The foxglove when given in very large and quickly repeated doses, occasions sickness, vomiting, purging, giddiness, confused vision, objects appearing green or yellow; increased secretion of urine, with frequent motions to part with it; slow pulse, even as low as 35 in a minute, cold sweats, convulsions, syncope, death. . . . I am doubtful whether it does not sometimes excite a copious flow of saliva."

This discerning description applied to the effects of large acute doses because

Withering was unacquainted with the prolonged use of maintenance amounts of foxglove. Digitalis poisoning, as usually encountered today, is due to the continued ingestion of the drug in amounts greater than are destroyed or eliminated. The glycoside accumulates in the body and perhaps especially in heart muscle.

Gastro-intestinal Effects. Anorexia, nausea and *vomiting* are among the earliest evidences of digitalis overdosage. The emetic effects of the cardiac glycosides were known for centuries, and squill in particular was used as an emetic. Withering recognized that vomiting did not occur immediately upon taking foxglove and that this was an untoward side-action of the drug.

Anorexia usually occurs a day or more before nausea and vomiting develop. It then remains more or less constant until digitalis is stopped. Nausea next develops and may appear in recurring "waves." The significance of nausea as an early indication of digitalis toxicity should not be discounted. Salivation often accompanies the nausea and at times, as Withering noted, it may be copious. Vomiting then occurs but at times it may develop without preliminary anorexia or nausea. This is especially likely to happen if large doses are given rapidly. The episodes of nausea and vomiting may start and stop abruptly, only to recur with greater severity. Nausea and vomiting may be transitory or entirely absent in some patients, and one should not rely on these signs alone to ascertain whether or not overdigitalization has occurred. The fact that the same digestive derangements are noted in patients with heart failure is, of course, no deterrent to the use of digitalis. Parallel with the restoration of compensation comes relief from the anorexia, nausea and vomiting due to heart failure.

Diarrhea may also be noted and rarely it may be the only gastro-intestinal manifestation of digitalis overdosage. The mechanism of the diarrhea is unknown but it may well be the same as that for vomiting. *Abdominal discomfort or pain* often accompanies the gastro-intestinal symptoms. The total dose of digitalis which must be given before nausea and vomiting appear varies greatly (1.25 to 8.5 grams of the powdered leaf) but in general is no different in normal patients than in those with heart failure. Once the drug is stopped, gastro-intestinal symptoms disappear in a few days. In a few patients with severe heart failure, optimal therapeutic effects of digitalis may not be obtainable unless amounts of the drug are given which for a time produce episodes of nausea and vomiting or other evidence of toxic action.

The *mechanism* of the nausea and vomiting caused by cardiac glycosides has been the subject of considerable investigation. In former years it was believed that gastric irritation from the crude drugs caused the symptoms, and this notion is still exploited by some firms who claim that their preparations are "non-emetic." It is clear, however, that vomiting occurs only late in the course of digitalization and can be produced both clinically and experimentally in animals by the parenteral administration of digitalis. Likewise it is demonstrable that vomiting movements result even though the entire gastro-intestinal tract has been removed. These observations definitely eliminate local irritation as a factor and place the mechanism somewhere in the nervous system, probably in the medullary emetic center. Hatcher and Weiss (1922) showed that digitalis does not act directly on the medulla to cause emesis, and that by sectioning the cardiac nerves in the cat vomiting can be abolished. They concluded that the drug excites the central vomiting mechanism only through afferent stimuli arising from the overdigitalized heart. These stimuli are carried mainly by way of the sympathetic afferent fibers but also to a certain degree by the vagi. Although this explanation has been challenged, the bulk of clinical and experimental evidence points to the fact that the *vomiting is reflex in origin* and arises neither from irritation of the alimentary tract nor from direct stimulation of the medulla. The exact site of origin of the afferent stimuli in man may require further elucidation. That the heart is the source has been seriously challenged by the experiments of Dresbach (1939).

Cardiac Effects. The alterations in cardiac rate and rhythm occurring in digitalis poisoning may simulate almost every known type of arrhythmia seen clinically. Before deciding whether digitalis or an exacerbation of the patient's disease is the cause, one must marshal all the available evidence concerning the nature of the heart disease, the cardiac status before the drug was given, the doses used and the response manifested during the period of digitalization. When sufficient information is not obtainable, the electrocardiogram may at times be helpful. In particular, the P-R interval and the character of the T waves may assist in deciding whether digitalis is responsible.

Extrasystoles. Probably the most frequent cardiac effect of digitalis overdosage is the occurrence of extrasystoles. These originate most commonly in the ventricle but can arise from the auricle. The cause of the ectopic beats is the increased irritability of the myocardium produced by excessive amounts of digitalis. If the extrasystoles are frequent, the ventricular rate increases and overshadows a primary slowing due to a toxic depressant action of the glycoside on the rate of impulse discharge by the S-A node. If the extrasystole recurs after each regular systole, digitalis "coupling" is present (pulsus bigeminus) (Figure 52). This is particularly likely to occur in patients with auricular fibrillation and fortunately permits the recognition of overdigitalization, because ventricular ectopic beats may sometimes be difficult to detect in this arrhythmia.

The occurrence of ectopic beats does not in itself always signify that digitalis dosage must be curtailed. In some patients relatively small doses may cause this sign to appear. The existence of extrasystoles before digitalis is given does not contraindicate the drug, which indeed may decrease the number of the abnormal beats.

Cardiac rate. Although the ventricular rate may be increased by digitalis if numerous extrasystoles appear, it may also be slowed either through a direct

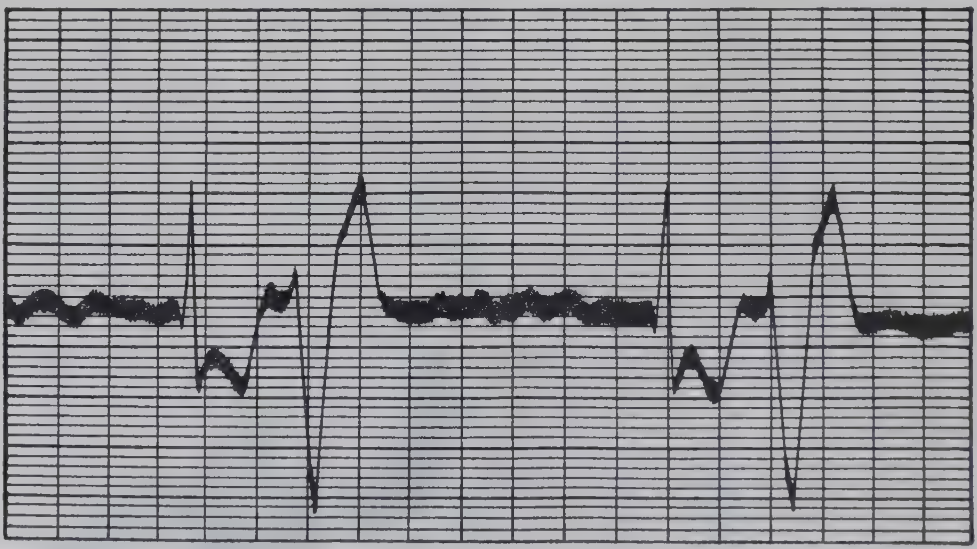

FIGURE 52. *Advanced digitalis intoxication.*

Male, aged 75, arteriosclerotic heart disease and auricular fibrillation. ECG: Lead 2. Note the marked depression of the RS-T segment in the "normal complexes" (the first and third), and the ectopic ventricular beat which follows each of these complexes. This is an example of "digitalis coupling." (Courtesy of Dr. A. J. Geiger, Yale University School of Medicine.)

action on the S-A pacemaker or on the A-V conduction system. Slowing due to a direct action of digitalis on the pacemaker requires very large amounts of the drug. Ventricular escape and rarely auricular standstill may result. Toxic amounts of digitalis may cause sufficient prolongation of A-V conduction to produce dropped beats and at times complete auriculoventricular dissociation (Figure 53). Lesser grades of depression of conduction do not result in cardiac slowing but higher grades occur with excessive doses of digitalis and often indicate previous disease of the conduction system. Partial or complete A-V block must always be viewed as evidence of the toxic action of digitalis. The usually accepted rule is to stop digitalis if the ventricular rate falls to 60 beats per minute or below. *It must be remembered, however, that the heart rate may not be slowed at all by digitalis and that an increase in rate may be the first evidence of digitalis poisoning.*

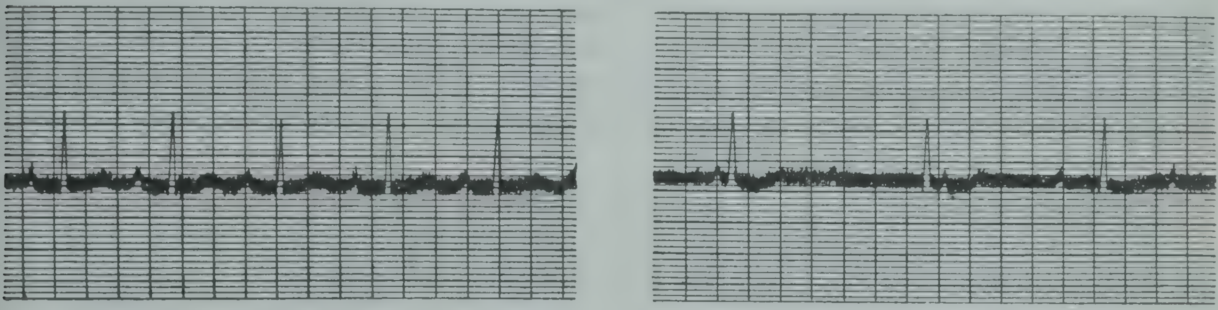

Figure 53. *Effect of digitalis on the conduction system.*

Female, aged 60, arteriosclerotic heart disease. ECG: Lead 1. *Left:* Before digitalis, incomplete A-V block; P-R interval, 0.24 second. *Right:* Same lead, after 2.0 grams digitalis in 18 days. Complete A-V block with dissociation of auricular and ventricular activity, presumably due to digitalis intoxication. Note that the previously upright T-wave has been replaced by a very shallow negative dip of the RS-T segment, also probably as an effect of digitalis. (Courtesy of Dr. A. J. Geiger, Yale University School of Medicine.)

Arrhythmias Due to Digitalis. Sinus arrhythmia occurs as an early and minor toxic effect of digitalis. It is noted especially in the young and can be abolished by atropine, signifying that vagal stimulation is probably the basis. *Paroxysmal tachycardias* from digitalis may arise either from the ventricle or auricle and call for discontinuance of the drug. *Auricular tachycardia* usually arises from an ectopic focus in the auricular muscle rather than from the S-A node. *Ventricular tachycardia* from digitalis is always serious and calls for immediate cessation of the drug because ventricular fibrillation may ensue. A particularly ominous type of ventricular tachycardia which is thought to signal the approach of fatal fibrillation of the ventricles is characterized by alternation in the direction of the Q-R-S complexes in the electrocardiogram (Marvin, 1928). Though this usually occurs in badly injured hearts, it is apparently specifically produced by digitalis (Figure 54).

Auricular fibrillation can be caused by large doses of digitalis (Tung, 1936). This result is sometimes sought in the therapy of auricular flutter. The occurrence of this arrhythmia usually but not always calls for temporary cessation of digitalis. That digitalis overdosage can cause fibrillation of the auricles is not a deterrent to the use of the drug in this disorder. *Ventricular fibrillation* is undoubtedly the commonest cause of death from digitalis poisoning. It is preceded by ventricular extrasystoles. Sudden death in patients receiving large amounts of the drug may well be due to this arrhythmia. It is particularly likely to occur from the injudicious use of large intravenous doses of the cardiac glycosides.

Other arrhythmias seen after digitalis include *pulsus alternans, heart block* and *auricular standstill.* The two last named have been mentioned.

Cerebral Effects of Digitalis. Headache, fatigue, malaise and *drowiness* are quite common symptoms of digitalis overdosage and occur early. *Mental symptoms* include disorientation, confusion, aphasia, and even delirium and hallucinations. *Convulsions* have been known to occur. Such effects are particularly likely to develop in elderly arteriosclerotic patients and the exact rôle played by digitalis is uncertain. Fishberg (1938) states that in his experience complicating factors of dehydration, fluid and salt restriction, vomiting, or diuresis from salyrgan have been present and that improvement occurred when ample fluids were given and the mercury and digitalis stopped. Also, digitalis has been demonstrated in edema fluid and it has been suggested that the toxic effects of the drug may suddenly appear when this fluid is mobilized in diuresis (Schnitker and Levine, 1937).

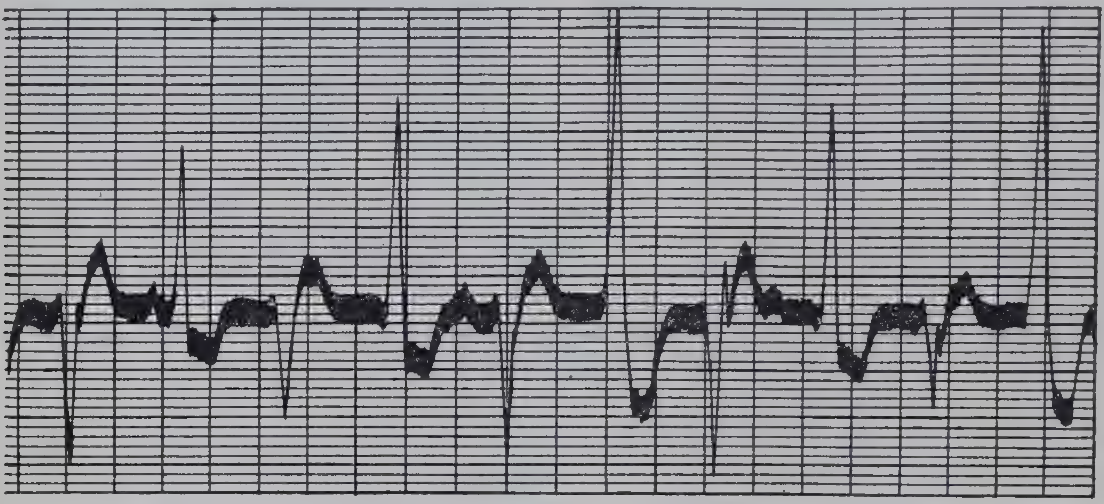

FIGURE 54. *Advanced digitalis intoxication.*

Male, aged 59, rheumatic heart disease with mitral and aortic stenosis and advanced congestive failure. Patient received 1.8 grams of digitalis in 24 hours. ECG: Lead 3, paroxysmal ventricular tachycardia with regular alternation in the direction of the ventricular complexes. Auricular rate, 94 per minute; ventricular rate, 138. Note especially the differences in size and shape of the ventricular complexes. Paroxysms of tachycardia like the one shown here recurred many times during the next four days and lasted from several minutes to several hours. The patient died four days after the tracing was taken. This type of arrhythmia is unusual and particularly ominous. Apparently it is seen only after excessive doses of digitalis. Marvin believes that the arrhythmia may represent ectopic beats arising alternately from the right and left ventricles. (After Marvin, 1928. Courtesy of the *American Heart Journal.*)

Vision. Vision is often blurred. White borders or halos may appear on dark objects ("white vision"). Color vision may be disturbed and objects appear yellow and green, or less frequently blue and red. Transitory amblyopia, diplopia and scotomata may also ensue. An explanation for these effects is not available.

Eosinophilia and Skin Rashes. These rare reactions to digitalis may be accompanied by refractoriness to the cardiac effects of the drug. The skin lesions may be urticarial or scarlatiniform in character. The increase in the number of eosinophils may be quite pronounced. Atropine has been known to lower the level of eosinophils and pilocarpine to elevate it (Romano and Geiger, 1936).

Bio-assay of Digitalis Preparations. Because the crude powdered leaf of digitalis varies in potency, physiological standardization of digitalis preparations is necessary. No acceptable chemical method of assay is yet available. Standardization is performed in several different ways.

The *official method* is that of the U.S.P. XI (1936) which requires that the digitalis be assayed on *frogs* and that the reference material used be a *Standard Reference Digitalis,* the strength of which, in relation to the *International Standard Digitalis Powder,* is known. This technic involves the injection of a suitably prepared tincture of the reference digitalis under standard conditions into the ventral lymph sac of frogs and the end-point is the systolic arrest of the ventricle in one hour. One *U.S.P. Digitalis Unit* or *International Digitalis Unit* is the equivalent of 0.1 gram of the International Standard Digitalis Powder. The B.P. also employs the International Digitalis Unit as its standard. Many objections have been raised to the U.S.P. frog method, among them being that a toxic action is measured and that the amphibian heart is far removed from the mammalian heart.

Other assays, not official in the U.S.P., have been devised and one commonly employed is the *cat method* of Hatcher and Brody. This involves the intravenous injection of the drug and the end-point is the death of the animal in one and one-half hours. The authors of the method discovered that the minimal lethal dose of ouabain for cats is almost uniformly 0.1 mgm per kg and that better results are forthcoming if ouabain is also injected. After a given amount of the unknown digitalis preparation has been administered, ouabain is given slowly until death occurs. The difference between the theoretical lethal dose of ouabain and the actual amount of ouabain used represents the part contributed by digitalis, the potency of which is then known in terms of ouabain. By this method, one *cat unit* represents the potency of an amount of digitalis which is lethal to one kg of cat.

Still other technics of bio-assay are used. Some are variants of the frog and cat methods described, and the units consequently vary with the particular modification employed. One of the better known modifications of the Hatcher and Brody cat method of assay is that of Magnus and Van Wyngaarden. This technic employs artificial respiration which permits the cat to tolerate a much larger dose of digitalis. The cat unit (Magnus) obtained by this assay thus represents a larger amount of drug than does the Hatcher-Brody cat unit. Other technics employ various species of animals. The *lethal dose assay in guinea pigs* and the *pigeon emesis method* are two which have received particular attention.

Unitage. It is important for the clinician to appreciate the change in digitalis unitage (and hence dosage) brought about through the adoption by the U.S.P. XI of the International Digitalis Powder as the standard of potency. This occurred as a result of a desire to conform to international standards of drug potencies as urged by the League of Nations Health Committee. The International Digitalis Powder proved stronger than the U.S.P. X digitalis which was official between 1926 and 1936. As a result, *U.S.P. XI digitalis is from 25 to 30 per cent stronger than the U.S.P. X digitalis and the dose must therefore be reduced proportionately, that is, by about 20 per cent* (Edmunds, 1939).

Digitalis dosages referred to in the clinical literature between 1926 and 1938 are largely based on U.S.P. X digitalis. Now that the U.S.P. XI digitalis is available on the market, it is essential to appreciate that the doses formerly prescribed (U.S.P. X) are too large by about one-fifth and that overdosage and digitalis intoxication may result unless confusion is avoided. Reports of overdigitalization have already appeared due to this error. The difficulty lies in the fact that a considerable amount of U.S.P. X digitalis is still being marketed. It is incumbent upon the physician to know the potency of the digitalis which he is employing and the method by which it was standardized, and a patient whose optimal maintenance dose is well regulated on one product cannot be shifted indiscriminately to another preparation of different potency. If the cat unit is preferred to the U.S.P. digitalis unit, one must know the potency of the particular cat unit which is used.

An important point to bear in mind is that bio-assay is subject to considerable variation and that two methods of digitalis assay may give discordant results when compared with each other. For this reason, the Council on Pharmacy and Chemistry does not require pharmaceutical firms to assay their digitalis preparations by two different methods, and the N.N.R. includes drugs assayed by any single method acceptable to the Council. The physician may therefore expect to find some variation in potency between different commercial products, and he would do well to restrict his choice to a single preparation or a few satisfactory preparations, with which he has become familiar, rather than to use without discrimination a large number of digitalis preparations and purified principles which are available. *In the last analysis, clinical assay of any particular product must be done on the patient.* Individuals vary so greatly in their response to and requirement of digitalis that one must look to the patient in order to determine the dose of digitalis.

The term "cat unit" is becoming more and more ambiguous and confusing, and it would probably be best if digitalis potencies were always expressed in terms of official U.S.P. units. However, inasmuch as many firms assay and market digitalis products in terms of "cat units," many physicians have become accustomed to think in terms of these units when prescribing for patients. The "cat unit" derived by the original Hatcher-Brody assay fortuitously represented almost the exact amount of digitalis in 0.1 gram (powder) or 1.0 cc (tincture) of U.S.P. X digitalis. This fact allowed physicians a ready interconversion between "cat units" and 0.1 gram or 1.0 cc doses of U.S.P. X digitalis. For example, when it was finally established by the Council in 1924 that 1.5 grams (15 cc) of digitalis were essential for initial digitalization in the average patient, this same dose was referred to as 15 "cat units." Similarly, the average maintenance dose of digitalis of 0.1 gram (1.0 cc) once or twice daily was translated into one or two "cat units" daily. Due to the many variations of the original Hatcher-Brody method, however, and the resulting multiplicity of "cat units," one cannot assume that an amount of digitalis representing the "cat unit" of one drug distributor is exactly the same as that of another, unless identical methods of assay are known to be employed. The interconversion between "cat units" and U.S.P. digitalis units has become more difficult due to the increased potency of U.S.P. XI digitalis as compared with the U.S.P. X. Indeed, such interconversion serves no useful purpose. The original Hatcher-Brody cat unit has not changed because the sensitivity of cat hearts to the glycoside has not changed but the amount of digitalis powder which it represents depends upon whether it is being measured in terms of U.S.P. X or U.S.P. XI digitalis.

Preparations Available for Clinical Use. Many digitalis and digitalis-like drugs are available to the physician. It may be said at the outset that the safest method of administering digitalis is to use a well-standardized tincture or powdered leaf. Withering, after exhaustive trials of various foxglove preparations, finally decided on the powdered leaf. All digitalis-like drugs manifest the same type of cardiac activity and it has not been conclusively demonstrated that the various digitalis substitutes or fractions have any clinical advantage over the galenical preparations. Another important point is that of cost, because digitalis medication must often be continued for years and the purified proprietary products are quite expensive. Preference should be given to the official U.S.P. and B.P. preparations of digitalis. Galenical preparations act quickly and effectively, are readily available and relatively inexpensive. They can be prescribed as the official tincture or powdered leaf.

Powdered Digitalis, U.S.P., B.P. The source, composition, assay and unitage of powdered digitalis leaf have been described. When "digitalis" is prescribed without further designation, the official powdered leaf is dispensed by the pharmacist. The powder can be administered in pill, tablet, capsule or suppository form.

Tincture of Digitalis, U.S.P., B.P. This is the only acceptable liquid preparation of digitalis. One cc of the tincture is equal in potency to 0.1 gram of powdered digitalis (one U.S.P., B.P. or International Digitalis Unit). The *Infusion of Digitalis* (N.F.) is an unstable aqueous preparation which should not be employed.

Strophanthus, N.F., B.P. The source and composition of strophanthus have been described. It has no advantage over digitalis and is seldom used. The intestinal absorption of powdered strophanthus and the *Tincture of Strophanthus* (N.F., B.P.) is unpredictable, and diarrhea is frequently noted after their ingestion. Galenical preparations of strophanthus have no place in modern therapy.

Squill, U.S.P., B.P. The use of squill or any of its official galenical preparations, such as *Syrup of Squill, Tincture of Squill* or *Fluidextract of Squill,* is obsolete. The source and composition of squill have been discussed.

In addition to the galenical preparations listed, purified glycosidal fractions of digitalis, strophanthus and squill are also available. Many of these are water-soluble and are advantageous when parenteral therapy is necessary. The official and more important of the N.N.R. purified fractions are as follows:

Strophanthin, U.S.P., B.P. (K-Strophanthin). This represents a mixture of glycosides obtained from *Strophanthus kombé* (Table 29). It consists of a white or yellowish powder which is soluble in water. Strophanthin is marketed in hypodermic tablets containing 0.3 or 0.6 mgm each. The drug is assayed in a manner identical with that for digitalis except that ouabain is employed as the reference material. Strophanthin is adjusted to have from 40 to 60 per cent of the potency of an equal weight of ouabain.

Ouabain, N.N.R. (Crystallized strophanthin, g-strophanthin). Ouabain is a crystalline glycoside obtained from *Strophanthus gratus.* Its chemistry has been described (Table 29). Ouabain is a reference standard in the U.S.P. and B.P., but is not in itself official. It is so slowly and irregularly absorbed from the intestinal tract that its oral use is unsafe. It is of value for parenteral administration, however, and being water-soluble it is marketed in sterile buffered solution in ampules containing 0.25 or 0.5 mgm per cc.

Digitoxin, N.N.R. Digitoxin is a purified glycoside obtained from *Digitalis purpurea* and is the chief active ingredient of digitalis, Its chemistry has been described (Table 29). Digitoxin is a colorless crystalline material, slightly soluble in water, and is marketed in tablet form for oral use and as a powder for rectal administration.

Scillaren-B, N.N.R. This preparation contains the amorphous component of the mixture of glycosides occurring in squill (Table 29). It is a water-soluble powder marketed for parenteral administration in sterile solution in ampules containing 0.5 mgm per cc. *Scillaren,* N.N.R., is essentially a mixture of scillaren-A and scillaren-B, and is marketed for oral administration in tablets (0.8 mgm) and solution (0.8 mgm per cc). *Urginin,* N.N.R., likewise is a preparation of squill glycosides for oral use and is marketed in tablets (0.5 mgm) and solution (1.0 mgm per cc).

Other N.N.R. purified proprietary preparations of digitalis leaf include *Digalen* (tablets and solution for oral use, and ampules for injection); *Digifoline* (tablets and solution for oral use, ampules for injection); *Digitalin* (French and German varieties; glycosidal mixtures not to be confused with the pure glycoside of the same name); *Gitalin* (said to be the purified glycoside of the same name; tablets for oral use). The descriptions of these appear in N.N.R.

The burden of proof that any of the digitalis substitutes or purified fractions is more valuable than the tincture or powdered leaf of digitalis lies squarely on the manufacturer making such a claim. Clinical evidence is against such contention. Furthermore it is misleading to insist that some of these drugs are less toxic or less emetic than others. The toxic actions of the cardiac glycosides are merely extensions of their therapeutic effects. The potency or toxicity depends not on the degree of purification but on the amount of drug given to the patient.

Stability of Digitalis Preparations. Powdered digitalis obtained from adequately dried leaves will keep for many years (16 in some cases) without significant loss of potency. The official tincture of digitalis, although not as stable as the powdered leaf, is still useful several years after preparation. When marketed in soft glass ampules, aqueous solutions of glycosides, such as ouabain or strophanthin and injectable digitalis fractions, eventually undergo deterioration from the alkalinity of the container. Hard glass or phosphate buffered solutions are therefore desirable. The powdered leaf, it appears, is superior in stability to any liquid preparation of digitalis (Haag, 1938).

Absorption, Fate and Excretion of Digitalis. *Absorption.* Digitalis given orally is adequately absorbed from the intestinal tract. The stomach does not participate in this absorption and the effect of the gastric juice on the drug is negligible. Local irritation is avoided by taking the drug with meals. Digitalis is well absorbed under nearly all circumstances, including chronic passive congestion of the enteric mucosa due to heart failure. Strophanthus and squill, on the contrary, are so irregularly absorbed that their oral use is dangerous and obsolete.

A single dose of digitalis is usually entirely absorbed within two hours and exerts its full action on the heart within six hours. This fact determines the interval between doses when the patient is being digitalized by the rapid method. Electrocardiographic evidence of initial myocardial action is detectable within two hours after a large oral dose of digitalis. That orally administered digitalis may not be completely absorbed, however, is suggested by the fact that smaller intravenous than oral doses are needed to produce comparable effects on the heart. When the glycosides are given by *vein,* initial cardiac action is noted within five to 15 minutes.

When given *subcutaneously* or *intramuscularly,* even purified digitalis preparations cause considerable pain and local reaction. Sterile abscesses may result and absorption is uncertain. Digitalis is readily absorbed from the lower part of the large bowel and *rectal instillation* therefore offers a valid means of administration if the drug cannot be taken orally.

Fate. The fate of digitalis in the body is unknown. The extracardial tissues, especially the liver and skeletal muscles, take up over 90 per cent of the drug mainly because of their bulk. Gram for gram, the heart muscle is thought to absorb more of the glycoside than any other organ of the body. Hatcher and Eggleston, (1919), however, were unable to demonstrate a selective storage of ouabain in any particular organ or tissue and are inclined to believe that a fairly uniform distribution of the glycoside occurs in the body.

Excretion. Digitalis is eliminated slowly from the body. With repeated doses, therefore, cumulative effects occur and eventually result in digitalis poisoning. After cessation of the drug, the cardiac actions persist for several days to three weeks or more. It is thus essential to know whether, when and how much digitalis has previously been given to a patient before administering additional drug. Strophanthin, in contrast to digitalis, is eliminated more rapidly so that the effects of a single full dose are dissipated in two to five days. It appears probable that thevetin is one of the most rapidly eliminated of the cardiac glycosides. The exact rate of excretion of digitalis is discussed later in connection with the maintenance dose.

The relative importance of destruction of cardiac glycosides in the body as compared with their excretion is unknown. Some of the drug is excreted unchanged in the bile and the urine but this represents only a small fraction of the total amount given.

Routes of Administration. *Oral.* The oral route of administration is used whenever possible. It is the least expensive and the safest, and absorption is sufficiently rapid so that early beneficial cardiac effects can be anticipated within two to six hours after large doses. Digitalis is usually given at meal time either as the tincture or as the powdered leaf in pill, tablet or capsule form.

Parenteral. The hypodermic injection of digitalis preparations is not advised due to the pain, local reactions and poor absorption characterizing this route of administration. When parenteral digitalis is necessary, the intravenous route is selected. This is only warranted when minutes rather than hours may spell the difference between life and death. Patients requiring intravenous digitalis are therefore moribund, and emergency measures such as venesection have failed to establish improvement. The preparations used are the strophanthin glycosides or the water-soluble, purified digitalis fractions. It is preferable to dilute the drug in isotonic sodium chloride solution and the injection is made *very slowly.* The dose must be carefully calculated and the facts concerning previous digitalis medication must be known. The intravenous route is by far the most dangerous and acute fatality may result from its use. Furthermore, the administration of parenteral preparations does not have the background of the large amount of clinical experience which has accumulated for the oral route of digitalis medication.

Rectal. If digitalis cannot be given orally, rectal administration is a satisfactory substitute. This may be needed especially if the patient is vomiting. A cleansing enema is given and the digitalis is then delivered through a small rectal tube. The preparations used rectally are the tincture of digitalis, diluted 1:7 so that the alcohol will not be irritating, or one of the Council-accepted water-soluble digitalis preparations (parenteral). Suppositories of powdered digitalis may also be employed. The doses, intervals between doses, and the time necessary for obtaining cardiac effects are the same for rectal as for oral digitalis medication.

Dosage: For Initial Digitalization. Digitalis dosage includes two problems, the amount needed to obtain therapeutic effects in a patient not previously receiving the drug (initial digitalization) and the amount needed to maintain these effects (maintenance dosage). Withering wrote, "I give to adults, from one to three grains of this powder twice a day. . . . About thirty grains of the powder . . . may generally be taken before the nausea commences." It is clear that the father of digitalis therapy understood that early toxic effects occurred when two grams (30 grains) of the powdered digitalis leaf were taken in the course of a few days.

In 1915, Eggleston radically changed the prevailing concepts of digitalis therapy by demonstrating that cardiac effects of the drug could be obtained within a few hours if large oral doses were used. Up to that time it was considered that several days were necessary before digitalization could be accomplished. Eggleston showed that full therapeutic or minor toxic effects appeared when about 15 (original Hatcher-Brody) cat units (15 cc of the U.S.P. X tincture; 1.5 grams of the U.S.P. X leaf) were given per 100 pounds of body weight. For the average 150 pound individual this dose would be approximately 20 cat units (20 cc tincture; 2.0 grams of the leaf). This could be given in divided doses over a period of one or two days dependent on the urgency of the case. It soon became apparent, however, that this dose level was somewhat high and represented an average that was not to be exceeded, rather than an optimal amount. Furthermore, body weight offered many obstacles to the calculation of dose by formula. Weighing the patient in the home is often impossible and it is not always easy to determine the edema-free weight.

A few years later, therefore, the report of the Council (1924; prepared by Robinson, White, Eggleston and Hatcher) established the following oral dose of digitalis which is the accepted practice today: "The total average dose of fairly active standardized digitalis by mouth for inducing full therapeutic effects within thirty-six to forty-eight hours in an adult who has not received digitalis within ten days is about 1.5 grams (=1.2 grams U.S.P. XI) * of the leaf or 15 cc (=12 cc U.S.P. XI) * of the tincture. The total dose may be divided into several equal parts given every four or six hours, or one-half or one-third of the total calculated dose may be given at once, and the remainder in two portions after intervals of four to six hours." It will be noted that no mention is made of body weight and that the rapidity of administration depends upon the patient's condition. If severe decompensation is present and digitalis has not been taken for the previous two weeks, one-third of the total dose (0.4 gram of the powdered leaf, U.S.P. XI; 0.5 gram, U.S.P. X) may be given immediately and repeated at six and again at 12 hours. The dose is then dropped to 0.08 to 0.16 gram, U.S.P. XI (0.1 to 0.2 gram, U.S.P. X) two or three times daily until optimal benefit is obtained and the maintenance dose can be adjusted. If one still feels that body weight is important and that a heavy patient requires more than the 1.2 grams of U.S.P. XI digitalis (1.5 gram, U.S.P. X), suggested above for initial digitalization, the dose level of 0.08 gram of powdered leaf, U.S.P. XI (0.1 gram, U.S.P. X), for each 10 pounds of body weight can be used.

If the physician is uncertain of the amount of digitalis taken by the patient within the previous week or two, the large doses outlined cannot safely be given. It is then best to administer 0.16 gram of the U.S.P. XI leaf (0.2 gram, U.S.P. X), three or four times daily and observe the patient closely for signs of intoxication before each subsequent dose is given. An interval of six to eight hours usually allows sufficient time for a single dose to take effect.

Intravenous Dosage. In the rare instances in which beneficial results must be obtained in minutes rather than in a few hours, intravenous medication may be given. In patients who have not received digitalis for two weeks, 0.25 to 0.5 milligram of *ouabain* or *strophanthin* may be injected. Rarely need this dose be repeated and it is best to complete the digitalization by giving 0.24 gram of the leaf, U.S.P. XI (0.3 gram U.S.P. X), orally every six hours until full benefit is secured. An alternate procedure is to continue with intravenous doses of 0.1 mgm of ouabain or strophanthin every half-hour until a total of 1.0 mgm of the glycoside has been injected. Oral or rectal medication, however, should be instituted as soon as possible. Cardiac glycosides must not be given intravenously to patients in whom a careful study of the heart has not been possible or who have been receiving digitalis within the previous 10 days.

Doses for Children. It is usually stated that children require more digitalis per pound than do adults, and that from 50 to 100 per cent more drug than calculated on the basis of body weight must be given to obtain results. As has been emphasized by Luten (1936), however, such estimates arise from the fact that heart failure in children is often an expression of active rheumatic carditis in which digitalis even in large doses may produce little benefit. Furthermore,

* Authors' insertion.

Luten points out that these large doses are often productive of toxic symptoms. It therefore appears that the type of heart disease rather than the age of the patient modifies the dose of digitalis required and that age itself is of secondary importance. Eggleston's studies also failed to reveal age as a significant factor in digitalis dosage, nor was sex found to be an important consideration.

Dosage: For Maintenance. Most patients receiving digitalis continue to require the drug for the remainder of their lives. It is therefore necessary to give digitalis daily in order to maintain the beneficial effects realized by the original digitalization. This requires that a sufficient amount be given to replace that which is destroyed or eliminated by the body.

Various attempts have been made to calculate this maintenance amount in order to arrive at an acceptable average daily dose of digitalis. Pardee (1919) gave digitalis to patients until emesis occurred, then stopped the drug for a few days and finally gave enough again to cause vomiting. The difference between these two amounts divided by the days during which no drug was administered gave a calculated average excretion rate of 1.2 cat units (approximately 1.2 cc or 0.12 grams, U.S.P. X) per day. Variations of from −55 per cent to +82 per cent, however, were noted. With a similar technic but employing electrocardiographic evidence of a definite level of digitalis action, Bromer and Blumgart (1929) arrived at an average daily excretion rate equal to a little over 1.5 cat units. From studies of this nature the statement has gained acceptance that the average adult excretes daily an amount of digitalis contained in 1.2 cc of tincture or 0.12 gram of powdered leaf, U.S.P. XI (1.5 cc or 0.15 gram, U.S.P. X), and that this amount therefore represents an average maintenance dose.

It was clearly established by the above investigations, however, that wide variations existed from patient to patient and that the maintenance dose bore no relation to body weight or to the type or severity of heart failure. Furthermore, subsequent studies showed the rate of excretion varied not only from person to person, but also in the same individual depending on the amount of drug in the body. The work of Gold and De Graff (1929, 1930) indicates clearly that the patient excretes not a fixed amount each day regardless of the dose given but rather a certain fraction of the amount present in the body. These investigators further pointed out that the rate of elimination tends to be a self-limiting process. If digitalis is started at a moderate dose level, the excretion rate is minimal at first and some of the drug accumulates in the body. As medication continues and more drug accumulates, the rate of elimination increases until equilibrium is reached, at which point excretion balances intake. Acceleration of excretion rate is definitely limited, however, and with excessive doses the drug accumulates in the body to the point where toxic symptoms occur.

That a fixed amount of digitalis is not excreted or destroyed daily but that increasing increments are eliminated as the drug accumulates in the body can readily be appreciated by consideration of the following example. Suppose that a patient who has not received digitalis previously is given 0.1 gram of the powdered leaf three times daily and full digitalization occurs on the fourth or fifth day. Suppose also that this patient is then found to require this same dose for maintenance therapy. It must be assumed that he is then excreting or destroying each day 0.3 gram of digitalis leaf, or intoxication would soon occur. If he eliminated daily this same fixed amount of drug during the initial few days of therapy, it obviously would not have been possible to digitalize the patient with the dose employed.

It is therefore impossible to employ any rule of thumb in reaching a daily maintenance dose of digitalis. The amount required varies with each case and depends upon the level of digitalis action desired. This level is usually that which allows *optimal digitalis effects.*

The Concept of Optimal Digitalis Effect and the Dose Necessary tc Maintain It. After the patient has been initially digitalized and optimal benefit obtained, the dose is adjusted to maintain this level of digitalis action. Most patients require about 0.8 cc of the tincture or 0.08 gram of the powdered leaf, U.S.P.XI (1.0 cc, 0.1 gram, U.S.P.X) once or twice daily. Others, however, may need as little as one-third or as much as four times this amount daily. It is important to understand that in most patients the optimal dose is definitely below that which will cause early toxic effects. It is therefore not necessary to increase the dose to the point of producing nausea and vomiting in order to find the optimal maintenance level.

In other words the ideal dose is not necessarily the largest dose tolerated. An amount is sought which will restore the highest degree of cardiac efficiency and relieve all symptoms and signs of heart failure. This dose is discoverable not by formula or in the electrocardiogram but in careful daily observation of the patient. It may be large or small and varies in the same patient according to changes in the condition of the myocardium. In some patients, especially those with severe heart failure, the optimal dose occasionally for a time may border on the toxic, and beneficial results will be obtainable only with amounts of digitalis which produce early symptoms of poisoning.

If the tincture is employed, calibrated medicine glasses or medicine droppers must be used to insure accurate dosage. The difference between minims and "drops" is particularly important in prescribing the small daily maintenance doses of tincture of digitalis. One can employ the isoalcoholic elixir to advantage by prescribing it as a vehicle for the tincture of digitalis so that a suitable dose of the latter is contained in each four or five cc of the mixture. A teaspoon or standardized vial known to hold this amount is then used by the patient and an exact dose of digitalis obtained in this manner (page 1321).

Therapeutic Indications for Digitalis

The Foxglove's leaves, with caution given,
Another proof of favouring Heav'n
Will happily display;
The rapid pulse it can abate;
The hectic flush can moderate
And, blest by Him whose will is fate,
May give a lengthen'd day.
William Withering.

Congestive Heart Failure. By far the most important use of digitalis is in congestive heart failure. The devious route by which this single clear-cut indication for the drug finally became definitely established has already been traced. Digitalis is useful regardless of whether the failure is predominantly of the left or right ventricle, or involves both sides of the heart. The type of rhythm exhibited by the decompensated heart neither indicates nor contraindicates the use of digitalis and the same statement holds true for valvular defects. Arrhythmias and valvular lesions may modify the response to, but they do not alter the indication for, digitalis if failure is present. In the last analysis, improvement of cardiac function by digitalis depends on the myocardial reserve. In badly damaged hearts, therefore, digitalization may not produce much benefit.

While it is true that the most dramatic responses are seen in patients with congestive heart failure and auricular fibrillation, excellent and equally significant results are obtained in cases of failure with normal rhythm and rate (Figure

50). Exertional and paroxysmal nocturnal dyspnea, cough, cyanosis, ascites, edema, and chronic passive congestion of the lungs and abdominal viscera are relieved. Diastolic size of the heart is decreased; venous pressure is lowered to normal; cardiac output, stroke volume and circulatory velocity are enhanced; and the diastolic rest period in each cardiac cycle is prolonged.

The rate of the ventricle may or may not be slowed. If tachycardia is present as a compensatory mechanism due to the failure, the rate of the heart slows as digitalis restores the functional efficiency of the ventricle toward normal. If auricular fibrillation is present, digitalis usually will slow a rapid ventricular rate only if the tachycardia is secondary to heart failure (Luten, 1936; Luten and Jeffreys, 1936).

The mechanism by which the direct myocardial action of digitalis brings about the restoration of cardiac compensation has been discussed. Once digitalis has returned the failing heart to a state of compensation, its continued use will do much to prevent the recurrence of heart failure.

Etiology of Heart Failure as a Modifying Influence on Digitalis Action. It is well known that the best results with digitalis are obtained when failure occurs in *hypertensive* or *arteriosclerotic* hearts. In decompensation due to *severe rheumatic myocarditis,* digitalis may give little or no relief. It has already been mentioned that digitalis may fail to restore compensation in children and this is due to the fact the rheumatic heart disease is prevalent in the young. Heart failure secondary to *cardiovascular syphilis* yields poorly to digitalis, especially if syphilitic aortitis is present. This is probably explained on the basis of the involvement of the coronary ostia by the syphilitic lesion. In other *infectious or toxic myocarditides,* such as diphtheritic heart disease, digitalis is not only ineffective but may actually be contraindicated. Heart failure occurring in *myxedema, hyperthyroidism,* and *thiamine deficiency* is not aided materially by digitalis.

In the so-called "heart failure" secondary to *shock,* and in *hypodiastolic failure* (Fishberg, 1938) due to cardiac compression from pericardial effusion or constricting adhesions, digitalis is of no value. The disturbance in function is not in the myocardium and the heart is involved only secondarily. In shock, digitalis may further decrease cardiac output and thus aggravate the syndrome. This also holds true for the type of *peripheral circulatory collapse* occurring in the course of acute infectious diseases.

Use of Digitalis to Prevent Heart Failure. Some authorities, notably Christian (1933), advocate digitalis as a prophylactic measure for patients in whom ultimate heart failure is a likely occurrence, especially elderly people with cardiac enlargement or hypertension. This promising field has been so little explored that sufficient clinical data are not yet available to decide on the value of digitalis as a preventive of heart failure. Also it should be remembered that the glycoside may decrease cardiac output in some patients with organic heart disease when heart failure is not present and this action may be detrimental to the patient (Stewart and associates, 1938). Many cases of auricular fibrillation with tachycardia, showing a minimal amount of failure and no discernible cause for the arrhythmia, are probably due to very early and occult decompensation of the ventricle. This etiology is particularly suggested if digitalis causes slowing of the heart rate. In such patients, the drug is undoubtedly valuable.

Auricular Fibrillation. This arrhythmia was at one time thought to be the main indication for the use of digitalis. It is now recognized, however, that the drug should be given only if heart failure is the cause of or accompanies the fibrillation. Cardiac failure and not the disorder of rhythm calls for digitalis. Indeed, if the disorder is due to toxic causes digitalis must be used with care, and even though decompensation is present the drug may fail to exhibit salutary effects. In some cases in which no cause can be found for the auricular fibrillation, digitalis may be used as a therapeutic test. If considerable slowing of ventricular rate occurs, occult failure as the basis of the arrhythmia is highly probable. Congestive cardiac failure is the most common cause of auricular fibrillation, however, and it is in such cases that digitalis is indicated and produces its most dramatic results.

The aim of digitalis therapy in auricular fibrillation with heart failure is to restore myocardial efficiency and an optimal ventricular rate, and to eliminate the pulse deficit (Figure 50). The mechanism of ventricular slowing by digitalis in this disorder has been fully discussed. If failure is not present, little effect on the ventricular rate will be noted, particularly in toxic cases where the drug may even be harmful. The decision to use the glycoside is therefore modified not only by the presence or absence of failure but also by the presence or absence of a toxic basis for the fibrillation. Digitalis is particularly needed in non-toxic cases with failure; it may be contraindicated especially in toxic cases without failure, as in thyrotoxicosis and diphtheritic heart disease.

The fibrillation of the auricle is not halted by digitalis. The auricular rate may increase or decrease but it is usually speeded both by the muscular and vagal effects of digitalis. Both digitalis and quinidine increase the refractory period of and slow the rate of conduction in auricular muscle but accomplish this by entirely different means. It may be asked legitimately, therefore, why digitalis does not stop auricular fibrillation. The answer must lie in the fact that the glycoside does not sufficiently lengthen the refractory period of auricular muscle to interrupt the circus movement. Such an action of digitalis can arise only from an increase in the force of auricular contraction. Digitalis may not be able to accomplish this in a dilated fibrillating auricle. Furthermore, larger doses increase muscular irritability and thus shorten the refractory phase. Likewise vagal stimulation caused by the drug also tends to shorten the refractory period. These combined effects fix and perpetuate, if not actually accelerate the rate of, the auricular fibrillation. Therefore the action of digitalis on the ventricle, not on the auricle, is sought in this disorder.

Auricular Flutter. Digitalis has the same indications and mechanism of action in auricular flutter as in auricular fibrillation, and the foregoing discussion of the latter arrhythmia applies here. The ventricular rate is slowed if failure is present, but in addition the action of digitalis on the conduction bundle comes into play as previously described.

It is sometimes possible to convert the flutter to fibrillation by large doses of digitalis. This is accomplished by combined muscular and vagal effects of the drug to shorten the refractory period of auricular muscle and therefore to increase the rate of circus movement. The large doses needed for this purpose usually result in toxic symptoms and cause a high grade of A-V block reaching 4:1 or higher. The ventricular rate may fall to 60 or below. As soon as the flutter has been converted to fibrillation, the digitalis is stopped whereupon normal sinus rhythm may be established. This is thought to be due to the fact that a recently produced fibrillation tends to stop when the exciting cause is removed. In this instance, the exciting cause is digitalis. In many cases, however, the fibrillation persists or reverts to flutter. In any event, the slower ventricular rate is beneficial. If auricular flutter or fibrillation persists, chronic medication with digitalis is adopted to maintain an optimally efficient ventricular rate.

Paroxysmal Tachycardia. Although digitalis can produce this disorder as a toxic effect and should be stopped when it occurs, nevertheless in certain cases of supraventricular (nodal or auricular) origin the drug may successfully terminate an attack. The tachycardia is first slowed and then aborted. Mecholyl and carotid sinus pressure, however, are to be tried first. If these fail, quinidine may be employed before digitalis is used. Digitalis should not be prescribed if tachycardia is of ventricular origin. The necessity for terminating an episode of tachycardia lies in the fact that, if prolonged, heart failure and death may occur.

Special Factors Modifying Digitalis Therapy

Coronary Thrombosis. Coronary occlusion in itself is not an indication for digitalis. Digitalis is contraindicated during the first few days following an acute coronary thrombosis. The clinical picture is usually one of shock rather than congestive heart failure, and digitalis, by further decreasing cardiac output, may make the patient worse. Again, the injured myocardium is quite irritable as evidenced by the occurrence of ectopic beats and abnormal rhythms. Under these circumstances digitalis may further increase the irritability of the myocardium and there is danger of precipitating ventricular tachycardia or fibrillation. It is also believed that the strong ventricular systoles promoted by the drug may strain the infarcted and friable myocardium undesirably, or tend to dislodge mural thrombi and thus cause embolism of pulmonary or systemic vessels. Digitalis is therefore not recommended unless progressive congestive failure ensues.

The dosage of digitalis in patients with acute coronary thrombosis must be carefully regulated, and rapid digitalization is usually unwise. There is some experimental evidence indicating an increased sensitivity of the injured myocardium to digitalis (Travell, Gold and Modell, 1938), and the drug should be given only in moderate amounts in order to meet this decreased tolerance. A reduction in dosage of at least 25 per cent should be observed until the patient's response is learned.

Angina Pectoris. Both experimental and clinical data apparently show that digitalis does not decrease coronary blood flow when given to man in therapeutic amounts. Indeed, in patients with heart failure, the restoration of efficient heart action may improve coronary circulation. Digitalis is not indicated in angina pectoris without heart failure. If failure is present, the coexistence of angina pectoris does not contraindicate digitalis. Cases have been reported in which digitalis was thought to have increased the frequency of attacks of pain. The explanation for this may be that cardiac output is probably decreased by the drug when failure is absent. It is also possible that digitalis, by restoring cardiac compensation in patients with angina pectoris and heart failure, allows a sufficient increase in physical activity to precipitate anginal attacks. It is well known, for example, that attacks of anginal pain are likely to disappear when congestive failure ensues, probably as the result of the restricted activity which decompensation imposes. The thorough studies of Gold and coworkers (1938) already referred to, however, do not allow the dogmatic conclusion that the drug directly influences either the incidence or severity of anginal attacks.

Pneumonia. There is no justification for the routine use of digitalis in pneumonia. The rapid heart rate, cyanosis, dyspnea, and other cardiovascular symptoms, as a rule, are not the result of cardiac decompensation. The heart is affected by the general toxemia and, unless there is failure, digitalis may do harm. The evidence strongly indicates that when digitalis is used routinely in patients with pneumonia, the mortality rate is definitely increased, and this fact applies as well to cases complicated with auricular fibrillation (Wyckoff and collaborators, 1930). Unless the incontrovertible indication exists for its employment, namely, congestive cardiac failure, digitalis should be withheld in pneumonia.

Thyrotoxicosis. The existence of hyperthyroidism in itself is not an indication for digitalis therapy. Tachycardia due to hyperthyroidism either with or without auricular fibrillation does not yield to digitalis therapy because it results from the action of the thyroid hormone on the heart and is not secondary to myocardial insufficiency (Figure 47). If heart failure is present, the drug is given just as if there were no thyrotoxicosis. The former practice of routinely digitalizing thyrotoxic patients before operation is losing favor. Rest in bed and medication with iodides and sedatives prior to thyroid resection usually have the desired salutary effect on the tachycardia. If auricular fibrillation occurs and persists despite surgical relief of hyperthyroidism, quinidine may be indicated.

Diphtheria. The heart injured by diphtheria toxin is more susceptible to digitalis and may be further harmed by the glycoside. If congestive failure is present in diphtheritic hearts, digitalis must be used with caution and in smaller dosage than usual. The drug in no way protects the heart against diphtheria toxin, is not indicated unless decompensation occurs, and offers little therapeutic promise.

Arrhythmias. There is no particular rhythm of the heart which indicates or contraindicates the use of digitalis. If heart failure is present, digitalis should be prescribed regardless of cardiac rhythm. The use of digitalis in the presence of paroxysmal tachycardia and fibrillation or flutter of the auricles has been discussed. In the presence of *partial heart block,* the drug may cause complete heart block but may be used if decompensation exists. Indeed, Blumgart and Altschule (1939), in a study of 19 patients with preexisting heart block, showed that digitalis can be given safely and optimal benefit obtained with doses which do not increase the grade of block. In *complete heart block* (auriculoventricular dissociation), digitalis may be employed safely and is indicated provided failure has occurred. The dosage used is often somewhat lower than that employed when block is not present. The idiopathic ventricular rate is usually not accelerated unless toxic amounts are given.

Valve Defects. There is no specific valve defect which indicates or contraindicates the use of digitalis. The status of the myocardium and not the valve lesion determines whether the drug is to be prescribed. The prejudice against using digitalis in aortic insufficiency had no basis in fact.

It is true that poorer results are obtained in heart failure associated with aortic lesions than with mitral lesions. Yet this may be explainable in part by the fact that many cases of mitral disease are rheumatic in origin and have auricular fibrillation accompanied by failure. These patients respond well to digitalis. On the other hand, a number of the cases of aortic insufficiency are due to syphilis and respond poorly to digitalis. The relative refractoriness of syphilitic hearts to digitalis has been mentioned.

Other Drugs. *Calcium.* Cases of sudden death have been reported from the intravenous injection of calcium salts in digitalized patients. Although the full significance of these reports or of the experimental work on the possible synergistic action of the two drugs cannot be stated, it appears safest for the present to use calcium by the intravenous route very cautiously if at all in patients receiving digitalis. If the cation is needed by vein, it should be injected very slowly. Several studies, however, seem to indicate that the effects of calcium and digitalis are neither potentiative nor even completely additive (Smith, Winkler and Hoff, 1939). The actions of calcium on the heart are presented elsewhere.

Ephedrine. There is some evidence that ephedrine and digitalis given together may prove more toxic than when the same dose of either is used singly. Until more information is available on this point, it seems wise to proceed cautiously with ephedrine medication in digitalized patients.

Quinidine. The circumstances under which digitalis may be combined with quinidine are described under the use of the latter drug in auricular fibrillation.

CHAPTER 29

QUINIDINE

History. Quinidine, an optical isomer of quinine, is one of the natural alkaloids found in cinchona bark. It was first described in 1848 by van Heyningen and was prepared and given its present name by Pasteur in 1853. Both quinine and quinidine are used for the treatment of malaria and it was noted a number of years ago that malarial patients who also had auricular fibrillation would occasionally be cured of arrhythmia by these drugs.

Wenckebach (1914) reported on the use of quinine alkaloids in certain cardiac arrhythmias. He relates the following experience (cited by Beckman, 1934): "In 1912, a patient presented himself in my office wishing to get rid of his attacks of auricular fibrillation. He knew that this was the so-called perpetual or complete arrhythmia and that his attacks ceased for the most part spontaneously after from two to fourteen days. He was a stout man, aged about fifty, able to do a good deal of bodily exercise and even during the attack to walk for four or five hours. From this fact it was clear that the efficiency of his heart and circulation was only slightly diminished by the attack. He did not feel great discomfort during the attack but, as he said, being a Dutch merchant, used to good order in his affairs, he would like to have good order in his heart business also and asked why there were heart specialists if they could not abolish this very disagreeable phenomenon. On my telling him that I could promise him nothing, he told me that he knew himself how to get rid of his attacks, and as I did not believe him he promised to come back the next morning with a regular pulse, and he did. It happens that quinine in many countries, especially in countries where there is a good deal of malaria, is a sort of drug for everything, just as one takes acetylsalicylic acid today if one does not feel well or is afraid of having taken cold. Occasionally, taking the drug during an attack of fibrillation, the patient found that the attack was stopped within from twenty to twenty-five minutes, and later he found that a gram of quinine regularly abolished his irregularity.

"I was greatly struck by this fact, and afterward tried this sort of treatment in many cases of auricular fibrillation. My success was disappointing, in that quinine abolished auricular fibrillation in only a few cases and in those cases only when the onset of this form was quite recent, never when it was of several years' duration. At the same time, I found that even in those cases in which auricular fibrillation was not abolished, the drug had a marked soothing action on the often terrific rate of the ventricle."

Frey (1918), impressed by the report of Wenckebach, studied quinine, cinchonine and quinidine in patients with auricular fibrillation and found quinidine to be the most effective.

Relative Importance of Quinidine. For every patient receiving quinidine for auricular fibrillation, at least a score are given digitalis. Nevertheless, when quinidine is used, it must be employed with a great deal of knowledge, for it is a dangerous as well as an effective drug. Therefore, quinidine will be discussed at length and this in turn offers an opportunity for correlating the physiology of auricular fibrillation with the pharmacodynamics of certain cardiac drugs.

Chemistry. Quinidine is the dextro-isomer of quinine and occurs with the latter in cinchona bark. The chemistry of the cinchona alkaloids is presented under quinine.

Comparison with Quinine. Quinidine shares many of the pharmacological properties of quinine. It is a "general protoplasmic poison" but is somewhat less toxic to unicellular organisms. Nevertheless, it has approximately the same antimalarial action as quinine, and is occasionally used in malaria when idiosyncrasy prevents the employment of quinine. Quinidine also has antipyretic and oxytocic actions. It is believed to be more toxic for man than quinine. This may be due in part to the fact that quinidine is employed in conditions the nature of which exaggerates the toxicity of the drug.

Both alkaloids are depressant to skeletal and cardiac muscle. The refractory phase is prolonged and the contractility is diminished. In comparison with quinine, quinidine affects the refractory period of cardiac muscle more than it affects the contractility. Therefore, quinidine is the cinchona alkaloid of choice in the treatment of auricular fibrillation.

Absorption and Excretion. Quinidine sulfate, the preparation usually employed, is readily absorbed from the intestinal tract. The major part is quickly excreted in the urine (Figure 56), mainly unchanged.

Pharmacological Actions. As has been stated, quinidine is a general protoplasmic poison similar to quinine. This action is due, at least in part, to a ferment-inhibiting property common to the quinine alkaloids. This inhibition extends to many enzymatic processes. It finds particular expression in the effect of quinidine on muscle, both skeletal and cardiac.

Skeletal Muscle. The action of quinidine on skeletal muscle is qualitatively similar to that of quinine and is described elsewhere (page 908).

Cardiac Muscle. The action of quinidine on the heart is the basis for its only therapeutic use other than for malaria. Therapeutic doses of quinidine produce changes in the heart which can be summarized as follows:

(1) *The refractory period* is increased, often as much as 50 to 100 per cent. Appreciation of the fact that quinidine prolongs the refractory period of the heart muscle is essential to an understanding of its cardiac action.

(2) *The myocardial excitability* is decreased, mainly due to the increased refractory period. Auricles and ventricles are affected in the same manner. This property of quinidine makes it of value in treatment of premature systoles.

(3) *The rate of the heart* is altered. If the rhythm is regular, the heart rate may be slowed. The slowing is not vagal in origin because it occurs after full atropinization. Indeed, some believe that the peripheral vagal mechanism is mildly paralyzed by quinidine. The bradycardia results from the action of the drug on the refractory period of the sinoauricular node where it decreases the rate of impulse formation. Large doses may even cause diastolic arrest.

(4) *The amplitude of contraction* of the compensated heart may be increased considerably by moderate doses of the alkaloid. This is due to the slower rate resulting in increased diastolic filling of the ventricles. Here again, the effect on amplitude is due to the increase in refractory period. With toxic doses or in heart failure, however, the cardiac excursion is not increased by quinidine and may be decreased, due to the depression of muscular contractility.

(5) *The conduction* of impulses in heart muscle is slowed by quinidine. The conduction between auricle and ventricle is retarded and various degrees of A-V

block may appear after large doses. Atropine does not alter this block. It is the slowing of auricular conduction, as described later, which tends in some cases to fix and perpetuate the circus movement of auricular fibrillation.

Auricular Fibrillation. Auricular fibrillation, by far the most common of all the permanent heart arrhythmias, is the disorder in which quinidine has unique value. In order to understand clearly the action and use of quinidine in auricular fibrillation, a brief description of the nature of the pathological physiology of this arrhythmia is necessary.

Clinically, there are two types of auricular fibrillation, the paroxysmal and the chronic. The paroxysmal form is usually associated with acute infections, hyperthyroidism, marked physical exertion, the use of alcohol, tobacco, anesthesia, epinephrine, etc. Its etiology may elude investigation. The chronic form of the disorder, which is the more common, usually results from permanent auricular strain. The chief physiological cause is increased intra-auricular pressure, and the chief clinical occurrence is in congestive heart failure. Occasionally, there is no detectable heart disease. Careful pathological examination of the auricles of patients who during life had long-standing auricular fibrillation reveals no unique or characteristic lesions that can be considered responsible for the onset or continuation of the arrhythmia.

Pathological Physiology of Auricular Fibrillation. Auricular fibrillation is a disorder of cardiac function due to alterations in conduction in auricular muscle and to changes in refractory period. These result in the replacement of orderly auricular contractions by a self-perpetuating circus movement composed of a central path about the origin of the great veins and collateral waves issuing from this parent path.

The *auricles,* for all practical purposes, are in "functional" diastole. They are markedly engorged and show rapid ineffectual fibrillary twitchings at the rate of 450 or more per minute (Figure 57).

The *ventricles,* fortunately, cannot respond to all these many impulses arising from the circus movement of the auricle, due in part to various degrees of auriculoventricular block, and to the refractory state of the ventricular muscle when many of these impulses arrive. The ventricular rate is usually 120 beats or more per minute. Characteristically, the ventricular contractions are totally irregular in force, rate and rhythm. A *pulse deficit* exists due to the inability of some ventricular systoles to raise the aortic valve leaflets. This is caused by the poor diastolic filling of the ventricles, due in turn to the irregular and rapid rate of contraction. The ventricular rate may be one and one-half times the pulse rate.

Auricular fibrillation is closely related to *auricular flutter* and *paroxysmal tachycardia.* Some believe that auricular flutter has a single and constant path for the circus movement, whereas auricular fibrillation has one major path and several vagarious collateral circuits.

Mechanism of Circus Movements in Muscle Rings and Application to Auricular Fibrillation. The basic abnormality of auricular fibrillation or flutter is a circus movement and it is therefore necessary to understand how such a movement originates and perpetuates itself, and how it may be stopped.

In 1908, Mayer experimented on circular strips of muscle from the umbrella of the jellyfish, and found that if a ring of muscle is stimulated so that the impulse travels only in one direction, a circus movement is established and may continue for many minutes or hours. Garrey (1914) and Mines (1914) showed that the same principles which underlie these simpler experiments applied also to auricular fibrillation. In order to establish a circus movement, the following conditions are necessary: (1) An area of muscle refractoriness must exist so that the wave of contraction can progress only in one direction and along one path. (2) This original refractory area must have recovered by the time the excitation process reaches it again, so that an "excitable gap" of tissue always exists. These facts are made evident in Figure 55 which represents simple circular muscle strips.

The main conditions, as outlined by Lewis, which tend to alter the excitable gap and hence the circus movement are shown in the following table:

Abolish gap and stop circus movement	*Increase gap and perpetuate circus movement*
1. Quicker conduction	1. Slower conduction
2. Longer refractory period	2. Shorter refractory period
3. Shorter path	3. Longer path

It is evident that the circuit time of the circus movement, that is, the time it takes to make one complete revolution, must always be greater than the refractory period of the muscle. A slowing of conduction naturally increases and a speeding of conduction decreases the circuit time.

These principles may more clearly be understood by an analysis of the following example. Suppose that the circumference of the muscular ring (depicted in Figure 55, C and D) undergoing the circus movement is 100 mm and that the contraction wave travels 500 mm per second. Then each circuit is made in 0.2 second. Now assume that the refractory period is 0.15 second; then any one point on the muscle ring recovers from its contraction when the next impulse is 0.05 second or 25 mm distant. Therefore, a 25 mm portion of the muscle ring will again be ready to contract and this represents the "excitable gap."

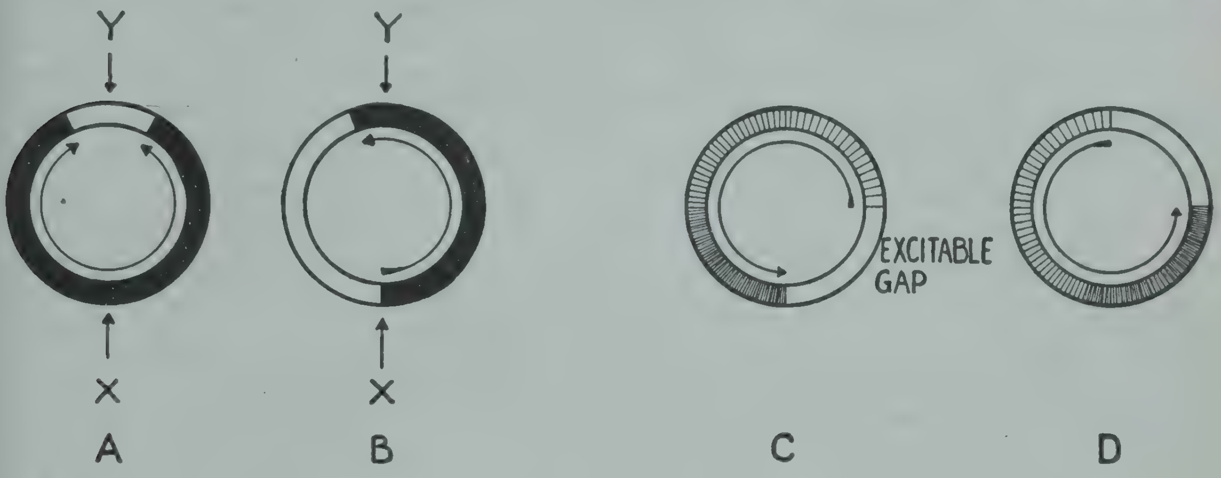

Figure 55. *Mechanism of circus movement.*

Solid black indicates refractory muscle; unshaded area signifies excitable muscle. Curved arrows show direction of contraction waves. *A.* If a stimulus is applied at point X to a circular strip of muscle, a wave of contraction is initiated which passes in both directions. When point *Y* is reached, the waves of contraction cease because the areas contiguous to *Y* are still refractory from having just contracted. *B.* If the wave of contraction can pass in only one direction from point *X*, it will make a complete circuit along the strip of muscle. If by the time point *X* is again reached this region has recovered its excitability, the circus movement will continue to travel the muscular circuit over and over again. *C.* The unshaded portion represents the excitable gap, that is, the area of muscle which has recovered from the previous wave of contraction. An excitable gap must always be present or the circus movement is automatically blocked. The intensity of shading indicates the degree of refractoriness of that portion of the ring of muscle which has not yet recovered from the wave of contraction. The head of the circular arrow shows the advancing margin of the contraction wave. *D.* Same ring of muscle as shown in *C,* but depicted a fraction of a second later.

If conduction is slower, the impulse arrives later and the muscle has even more time to regain excitability. The circus movement is perpetuated in this manner. If the refractory period is increased, it takes longer for the muscle to recover, and the impulse now finds the tissue inexcitable. In this way, the circus movement is blocked. In the example given, the circus movement could be stopped either by lengthening the refractory period from 0.15 second to 0.20 second, or by increasing the rate of conduction to 670 mm per second.

This information may now be applied to clinical auricular fibrillation. The normal rate of impulse conduction in auricular muscle is 1000 mm per second, but in the fibrillating auricle this rate is reduced to 500 mm per second. The refractory period of normal auricular muscle is about 0.20 second in duration, with cardiac rates up to 100 beats per minute; but, if the auricle is fibrillating, this refractory period is reduced to about 0.10 second. The data available are presented in Table 31 (modified from Wright, 1936).

Inspection of the data in Table 31 indicates that a therapeutic agent can effectively block the circus movement either by increasing the refractory period or by increasing the speed of conduction. Unfortunately, there is no drug known which accomplishes both of these feats, because it is physiologically impossible to stimulate heart muscle in respect to one function (increased speed of conduction) and at the same time depress the heart in regard to another function (prolonged period of refractoriness).

Quinidine Action in Auricular Fibrillation. Quinidine acts in auricular fibrillation by increasing the refractory period of the auricular muscle. When the circus movement finds refractory tissue in its path, it comes to an end. As Osler phrased it, "The head of the circulating wave catches up with its tail." An increasing number of circulating impulses in the auricle are blocked when they find the auricular muscle inexcitable. Finally, they all die out and the auricle becomes quiescent. In this quiescent interval, the sinoauricular node once again resumes dominance and initiates normal rhythm. Occasionally, however, in the period during which the number of fibrillary twitchings are gradually diminishing, auricular flutter may intervene. This flutter may cause a marked increase in ventricular rate, which may be dangerous to the patient (Figures 56 and 57).

TABLE 31

DATA ON CIRCUS MOVEMENTS
OF AURICULAR FIBRILLATION AND FLUTTER
(After Wright, 1936.)

AURICULAR FIBRILLATION

Rate of auricular contractions	450 circuits per min.
Circuit time of each circus movement	0.13 second
Refractory period of auricle	0.09 second
Rate of conduction	500 mm per second
Length of path (circumference)	65 mm (0.13 x 500)
* Size of excitable gap	20 mm ($\frac{4}{13}$ x 65)

AURICULAR FLUTTER

Rate of auricular contractions	350 circuits per min.
Circuit time of each circus movement	0.17 second
Refractory period of auricle	0.11 second
Rate of conduction	500 mm per second
Length of path (circumference)	85 mm (0.17 x 500)
Size of excitable gap	30 mm ($\frac{6}{17}$ x 85)

* Because most of auricular muscle has a refractory period almost equal to the circuit time and not 0.04 of a second less, as given in the table, the excitable gap is not 20 mm but actually very small, so small indeed that the "crest of one wave rides close to and interlaces with the wake of the previous wave."

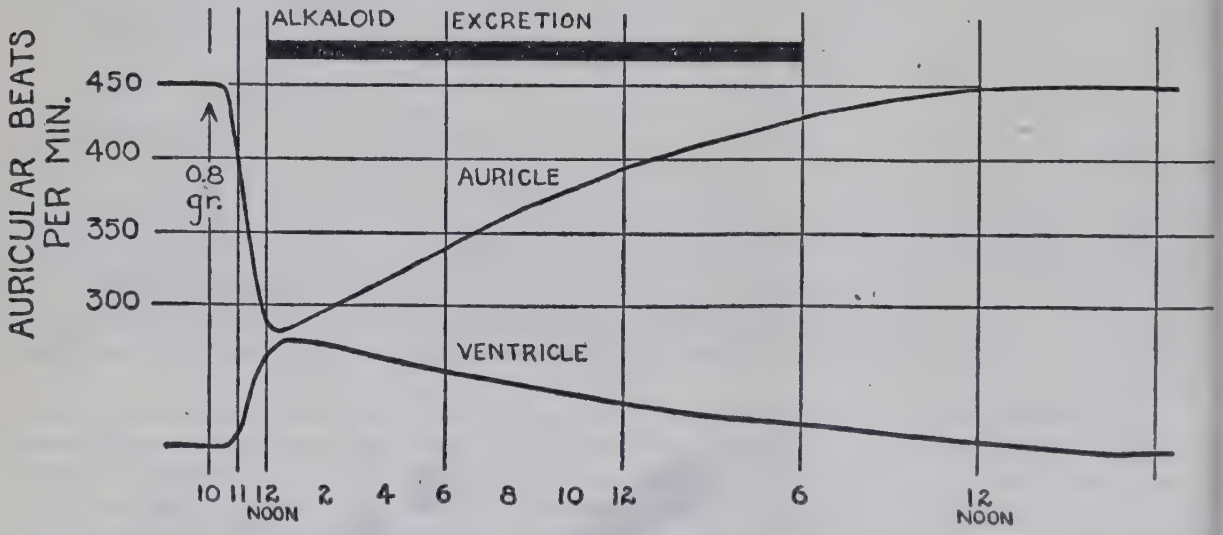

FIGURE 56. *The effect of a single 0.8 gram oral dose of quinidine on the auricular and ventricular rates in a patient with auricular fibrillation.*

The solid black line represents the period during which quinidine could be detected in the urine. Note that the peak effect of the drug on the heart occurs within two to three hours after administration, following which there is a gradual return to the original rates. Observe how closely the rise in ventricular rate mirrors the fall in auricular rate. Compare with Figure 57. (After Lewis, 1934. Courtesy of Shaw and Sons.)

This is because the ventricle responds to more auricular impulses as the auricular rate slows from one of fibrillation to flutter, especially if an A-V block of 2:1 grade intervenes. For example, a ventricular rate of 110 beats per minute may increase to 160, if quinidine causes a stage of auricular flutter with an auricular rate of 320 beats per minute.

Quinidine sometimes fails to stop auricular circus movement. This is because the drug also slows conduction in auricular muscle, and consequently each circus movement requires a longer time to complete its circuit. The muscle now has more chance to recover from its previous contraction and the arrhythmia may be perpetuated. If the action on the refractory period is greater, quinidine tends to stop the fibrillation. If the action to slow conduction is greater, quinidine tends to fix and perpetuate the fibrillation. The latter effect accounts for many failures in quinidine therapy.

Comparison of Quinidine and Digitalis in Auricular Fibrillation. Quinidine is used to cure auricular fibrillation by restoring normal sinus rhythm. Digitalis, on the contrary, does not cure auricular fibrillation. Under its influence the ventricles beat more slowly, more regularly and more efficiently. This is accomplished especially by the direct cardiotonic muscular action of digitalis, and also to some extent by its effects on the conduction of impulses from auricle to ventricle.

Both drugs produce longer refractory periods and slower conduction, but by very different mechanisms—digitalis by increasing the force of the myocardial contraction, and quinidine by depressing the restorative metabolism of muscle. The question is legitimately raised as to why digitalis does not cure auricular fibrillation. The answer to this is fully discussed on page 532.

Toxic Reactions. Not all the toxic reactions to quinidine occur as a result of the drug itself and some are due to the nature of the disorders for which quinidine is used.

Cinchonism. Quinidine, like most cinchona alkaloids, can cause the syndrome known as "cinchonism." This is fully described on page 910. Severe cinchonism, however, is fairly infrequent after quinidine.

Idiosyncrasy. Idiosyncrasy to quinidine is not rare and must be carefully tested for in each patient. The reaction consists of respiratory distress, occasionally with temporary cessation of respiration, cyanosis, dizziness, nausea and vomiting, and cold sweat.

Embolism. The appendages of auricles which have been fibrillating for months often contain more or less firmly attached mural thrombi. The sudden reversion to a normal rhythm produced by quinidine, with the resultant strong and complete contractions of the auricles, may cause these thrombi to be dislodged and to produce embolic occlusion of important vessels. Death may result. The attitude toward embolism caused by quinidine is changing and it is now believed that this danger has been overemphasized. Accidents of this sort are said by some to be no more frequent with quinidine therapy than with digitalis or no medication whatsoever.

Dangerous Tachycardia. As explained previously, when quinidine slows the rate of the fibrillating auricles to a point where the ventricles respond to more stimuli, that is, when auricular flutter replaces auricular fibrillation, there occurs a sudden marked tachycardia which may be serious (Figures 56 and 57). This can be largely prevented by previous digitalization of the patient.

Ventricular Standstill. Quinidine depresses the S-A and A-V nodes, and in the short period of auricular quiescence immediately after the cessation of the auricular circus movement, the pacemaker of the heart may not speedily resume its function. This may prove fatal.

Ventricular Fibrillation. Death from ventricular fibrillation after quinidine occurs more commonly than is usually stated, and many fatalities formerly attributed to embolism were probably due to ventricular fibrillation. This has been proved by electrocardiograms fortuitously taken immediately before death. That ventricular fibrillation can be produced by a myocardial depressant such as quinidine emphasizes the fact that this fatal arrhythmia can be caused by depressants as well as by stimulants.

Contraindications to Quinidine Therapy. There are many contraindications to the use of quinidine. Patients who develop severe cinchonism or have an idiosyncrasy to the drug should not receive it. Quinidine should not be used in the presence of acute infections or for patients with bacterial endocarditis. Severe cardiac failure or marked cardiac damage without failure (*e.g.,* coronary thrombosis) also limits its use. It should not be employed in patients with long-standing valvular disease or auricular fibrillation. Aged patients or those with marked cardiac enlargement or hypertrophy must be given quinidine cautiously if at all. Hyperthyroid patients with auricular fibrillation should not receive quinidine until after thyroid resection. A patient with angina pectoris whose pain was relieved by the onset of auricular fibrillation should not receive quinidine to revert his rhythm to normal. One who presents a history of embolic episodes cannot safely be treated with the alkaloid. Lastly, if complete heart block exists, there is nothing gained by attempting to restore normal auricular rhythm.

Many of the above contraindications are not absolute, and each case is a law unto itself. For example, auricular fibrillation of ten years' duration has been reverted to normal by means of quinidine. Furthermore, in certain hopeless cases of severe heart failure in which all other therapy has failed, quinidine may be used in spite of contraindications, and may occasionally stop the arrhythmia with beneficial results (Kohn and Levine, 1935). One may summarize the contraindications to quinidine by stating that the drug is not usually used (1) when there exist acute infective or toxic processes in the body; (2) if the heart is seriously damaged or in failure; (3) when the use of the drug is likely to cause a serious accident, such as embolism or idiosyncrasy, or (4) if the return to regular sinus rhythm is unlikely or not particularly desirable.

Indications for Use of Quinidine in Auricular Fibrillation. The best results from the use of quinidine are obtained in (1) young patients exhibiting little cardiac damage and in whom the arrhythmia is of recent origin; (2) cases of persistent auricular fibrillation after thyroidectomy, where results are truly brilliant; and (3) patients whose disorder causes intractable palpitation and whose chief complaint, even though they are digitalized, is a tumultuous beating of their hearts. In addition, as was stated, the drug is perhaps indicated where all other therapy has failed. In some clinics, quinidine is used as a prophylactic measure to prevent the onset of auricular fibrillation in cases of rheumatic mitral stenosis with frequent auricular extrasystoles presaging the onset of the arrhythmia. In small doses, the drug often causes the disappearance of these premature beats and perhaps delays the onset of auricular fibrillation.

Preparations. The official U.S.P. and B.P. preparation and the one commonly employed is *Quinidine Sulfate.* It consists of fine needle-like crystals which are odorless, very bitter to the taste and darken on exposure to light. *Quinidine,* N.N.R., the alkaloidal base, is also available.

Therapeutic Uses of Quinidine. *Auricular Fibrillation.* The patient with this type of arrhythmia who is to receive quinidine should be under close medical observation, preferably in the hospital. Two or three days of complete rest in bed with mild sedation should precede quinidine therapy. If the ventricular rate is above 90 beats per minute, the patient should be digitalized to lower this rate. Digitalis will also prevent ventricular tachycardia from occurring after quinidine

Technic. There are many different methods of administering quinidine, but the following is perhaps as safe and effective as any. A test dose of 0.2 or 0.3 gram of quinidine sulfate is given the day before therapy is started and the patient is carefully observed for symptoms of idiosyncrasy or cinchonism. The following day, 0.4 gram is administered every four hours, five times daily, starting at 8:00 A.M. This schedule is continued for seven to 10 days and comprises a "course" of quinidine.

One discontinues the drug if toxic signs or symptoms occur, if a tachycardia of over 125 beats per minute develops, or if obstinate auricular flutter appears. One also stops the drug upon the advent of showers of petechiae, which may signify the imminence of embolism, and premature ventricular systoles, which may presage ventricular fibrillation.

A second course of quinidine may be given after two or more weeks of rest if the first course was unsuccessful. The dosage system may now be altered. Digitalization should probably be instituted before quinidine is used a second time. The digitalis is usually stopped when the quinidine is started. A third and even a fourth course of quinidine may be given, with intervals of a month between trials. If still unsuccessful, the further use of quinidine is probably futile.

After normal cardiac rhythm is established, one gives 0.2 to 0.3 gram of the drug three times a day for one or two weeks. The dose is then gradually reduced over a period of several weeks. The daily maintenance dose varies greatly for each patient but is usually between 0.2 and 0.6 gram. In a few cases, no maintenance dose is necessary. This is particularly true in thyrotoxic patients after thyroidectomy. If auricular fibrillation recurs, courses of quinidine may be resumed but the time eventually comes when further attempts are unsuccessful.

Success in restoring normal rhythm by using quinidine depends upon the careful selection of cases and the proper dosage of the drug. About 65 to 80 per cent of all *properly selected and treated* cases can be reverted to a normal sinus rhythm (Stroud and Laplace, 1935; Fahr, 1938) (Figure 57). Unfortunately, in a number of these cases fibrillation may occur again within a few months. It is possible that this is due to a failure on the part of some of the patients faithfully to continue their daily maintenance dose. Fahr (1938) reports that quinidine therapy was successful in approximately 65 per cent of more than 500 patients with auricular fibrillation and that in nearly every case the arrhythmia did not recur if the daily prophylactic dose was taken. These results are considerably better than those reported by others. Some authorities maintain there is no good evidence that in the long run quinidine materially reduces mortality or prolongs life. Nor is it apparent that the chronic fibrillating heart, when adequately digitalized, is any less efficient than the heart restored to a normal sinus rhythm by quinidine. Nevertheless, some properly digitalized patients who are uncomfortable and restricted in their ability to perform physical exertion can be restored to a fairly active life after the auricular fibrillation has been abolished by quinidine therapy.

Before using quinidine, the physician must weigh the possible benefits to be derived against the possible dangers incident to the use of the drug. In some cases, such as in post-thyroidectomy patients in whom auricular fibrillation persists or in young persons with good heart muscle and fibrillation of short duration, there is no doubt that quinidine should be employed.

Auricular Flutter. Quinidine is indicated in this disorder but it is less effective in restoring auricular flutter to a normal rhythm than in cases of auricular fibrillation. It is possible that in auricular flutter the action of quinidine may be relatively greater on the conduction time of auricular muscle than on the refractory phase, which would tend to perpetuate the flutter and militate against success in reverting the rhythm to normal. Some cardiologists reserve quinidine therapy for those patients who fail to respond to digitalis.

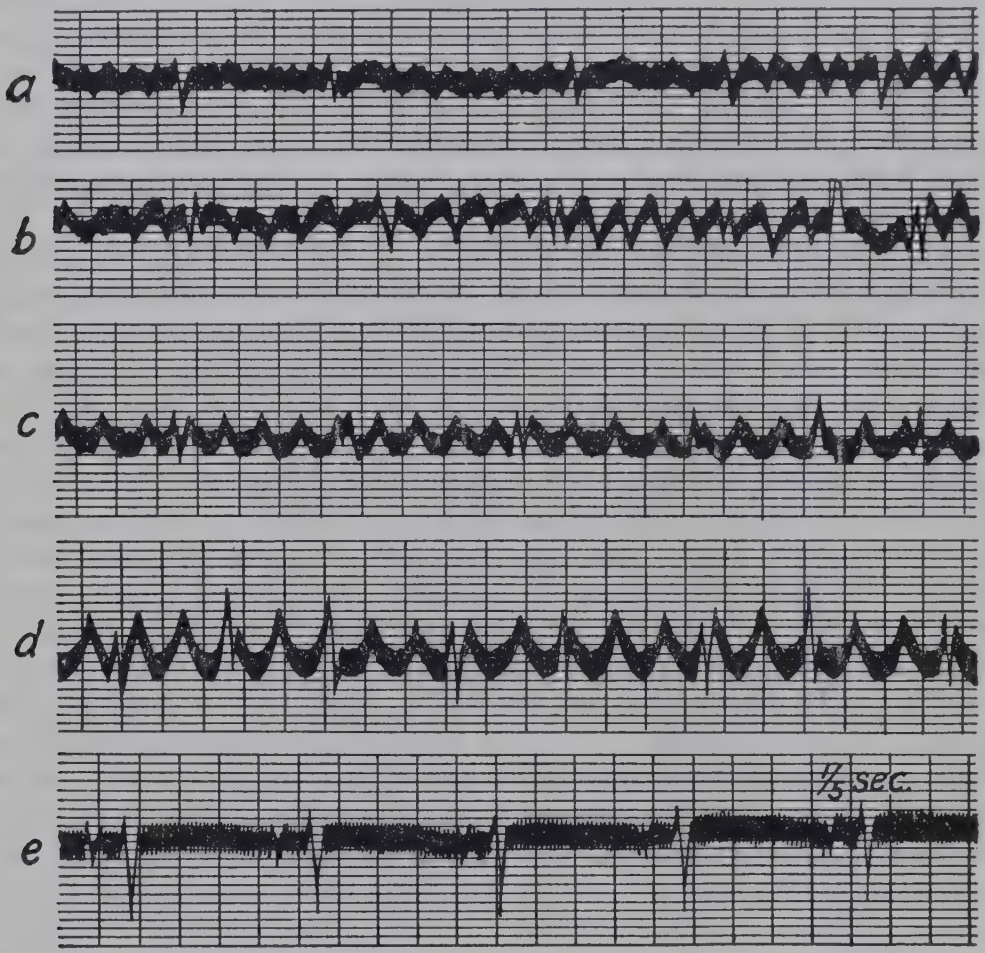

FIGURE 57. *Electrocardiographic changes noted during quinidine therapy of auricular fibrillation.*

Time in fifths of a second. (*a*) Before treatment: auricular rate of 450 beats per minute. (*b*) After one dose (0.3 gram) of quinidine: the auricular rate has fallen to 350. (*c*) At end of first day's treatment (after one gram of quinidine): the auricular rate has fallen to 296. (*d*) At the end of the second day's treatment (after two grams of quinidine): the auricular rate has fallen to 247, and the oscillations have become almost regular as in auricular flutter. Note the increase in ventricular rate. (*e*) Sixteen hours after the previous tracing (after 2.3 grams of quinidine): normal sinus rhythm has been restored. (After Lewis, 1937. Courtesy of Shaw and Sons.)

Paroxysmal Tachycardia. In paroxysmal tachycardia of *auricular or junctional origin,* quinidine probably acts by depressing the S-A node or an extranodal focus for the abnormal rhythm. The hearts of patients with this malady are usually in better condition than those with auricular fibrillation. Consequently the contraindications to quinidine are fewer and the dose is smaller, 0.3 gram being given three times a day, either to relieve or prevent paroxysms. For other therapy of this disorder, the index should be consulted.

In paroxysmal tachycardia of *ventricular origin,* quinidine may be effective in stopping as well as in preventing attacks (Fahr, 1938), and at times its action is dramatic and life-saving. The danger exists, however, that the drug may produce ventricular fibrillation in such cases.

Extrasystoles. Many measures are available if therapy is required for this disorder. Quinidine may be used to afford relief and acts by decreasing the muscular irritability which may be the basis for the extrasystoles. It can be employed in doses of 0.3 gram, two or three times a day. The drug is helpful in tiding a patient over a period of disagreeable cardiac consciousness, but he often stops the treatment voluntarily because it is more troublesome than the disability. The reassurance he obtains from the discovery that something can be done for him is nevertheless important.

Coronary Occlusion. Quinidine has been suggested for routine use in cases of coronary thrombosis to reduce muscular irritability and lessen the incidence of ventricular tachycardia or fibrillation. Ventricular fibrillation, however, is no longer considered a frequent cause of death in coronary occlusion. Furthermore, quinidine is a toxic drug, may in itself cause ventricular fibrillation, and should not be used for prophylactic purposes in patients with fresh myocardial damage.

CHAPTER 30

THE NITRITES

History. Glyceryl trinitrate was discovered by Sobrero in 1847. Amyl nitrite was first used in medicine by Guthrie in 1859. Both compounds were introduced in the 1860's for the treatment of angina pectoris, independently by Richardson and Brunton. The latter reported his work in 1867 and also described his experiences with amyl nitrite in his well-known textbook published many years later (1897), where he wrote as follows:

> "This drug (*amyl nitrite*) when inhaled causes very rapid dilatation of the vessels indeed, with flushing of the face, a feeling of fulness in the head, and a very great fall of the blood pressure. On account of this fall of blood pressure, it eases the heart at once when this organ is unable to overcome the resistance which is opposed to it. . . . When the heart contracts against a resistance which it cannot overcome, the pain in the heart . . . becomes great. You can readily see that the excess of work to be done over power to do it, which causes the pain in these cases, may depend upon the fact either that the peripheral resistance in the vessels has been increased above the normal, or that the power of the heart to overcome the resistance has been lessened below the normal. In either case, the resistance becomes too great for the heart. In cases of angina pectoris, this condition appears to obtain, and there you frequently find that there are both conditions to deal with, *viz.,* a heart which has become enfeebled and a resistance which has become increased above the normal.
